statements to oppose to these;* and, as we had occasion to observe when speaking of the neglect of bloodletting, we have no certainty that all the cases here enumerated were in reality pneumonic. At all events, later experience has proved that there is no advantage in the excessive doses here used, and, on the contrary, that greater success has resulted from more moderate quantities. The uncommonly small mortality of only two in fifty-seven, which Laennec asserts to have attended his method of exhibiting tartar-emetic, warrants our quoting his own account of his treatment, which will likewise show how much confidence he placed in the measure.

"As soon as I recognise the existence of the pneumonia, if the patient is in a state to bear venesection, I direct from eight to sixteen ounces of blood to be taken from the arm. I very rarely repeat the bleeding, except in the case of patients affected with disease of the heart or threatened with apoplexy or some other internal congestion. More than once I have even effected very rapid cures of intense peripneumonies without bleeding at all; but in common I do not think it right to deprive myself of a means so powerful as venesection except in cachectic or debilitated subjects. In this respect Rasori does the same. I regard bloodletting as a means of allaying for a time the violence of the inflammatory action, and giving time for the emetic tartar to act. Immediately after the bleeding I give one grain of the tartar-emetic dissolved in two ounces and a half of cold weak infusion of orange leaf, sweetened with half an ounce of syrup of marsh-mallows or orange-flowers; and this I repeat every second hour for six times, after which I leave the patient quiet for seven or eight hours, if the symptoms are not urgent, or if he experiences any inclination to sleep. But if the pneumonia has already made progress, or if the oppression is great, or the head affected, or if both lungs or one whole lung is attacked, I continue the medicine uninterruptedly, in the same dose, and after the same intervals, until there is an amendment not only in the symptoms, but also indicated by the stethoscopic signs. Sometimes even, particularly when most of the above-mentioned unfavourable symptoms are combined, I increase the dose of the tartar-emetic to a grain and a half, two grains, or even two grains and a half, without increasing the quantity of the vehicle. Many patients bear the medicine without being either vomited or purged. Others, and indeed the greater number, vomit twice or thrice, and have five or six stools the first day; on the following days they have only slight evacuations, and often, indeed, have none at all. When once the *tolerance* of the medicine (to use the expression of Rasori) is established, it even very frequently happens that the patients are so much constipated as to require clysters to open the body. When the evacuations are continued to the second day, or when there is reason to fear on the first that the medicine will be borne with difficulty, I add to the six doses to be taken in the twenty-four hours, one or two ounces of the syrup of poppies. This combination is in opposition to the theoretical notions of Rasori and Tommasini, but has been proved to me by experience to be very useful. In general, the effect of tartar-emetic is never more rapid or more efficient than when it gives rise to no evacuation; sometimes, however, its salutary operation is accompanied by a general perspiration. Although copious purging and frequent vomiting are by no means desirable on account of the debility and hurtful irritation of the intestinal canal which they may occasion, I have obtained remarkable cures in cases in which such evacuations had been very copious. I have met with very few cases of pneumonia where the patient could not bear the emetic tartar; and the few I have met with occurred in my earliest trials; insomuch that this result now appears to me to be attributable rather to the inexperience and want of confidence of the physician, than to the practice. I now frequently find that a patient who bears only moderately six grains with the syrup of poppies, will bear nine perfectly well on the following day. At the end of twenty-four or forty-eight hours at most, we perceive a marked improvement in all the symptoms. And sometimes even we find patients who seemed doomed to certain death, out of all danger after the lapse of a few hours only, without ever having experienced any crisis, any evacuation, or indeed any other obvious change, but the rapid and progressive amelioration of all the symptoms. In such cases the stethoscope at once accounts for the sudden improvement, by exhibiting to us all the signs of the resolution of the inflammation. These striking results may be obtained at any stage of the disease, even after a great portion of the lung has undergone the purulent infiltration. As soon as we have obtained some amelioration, although but slight, we may be assured that the continuation of the remedy will effect complete resolution of the disease, without any fresh relapse; and it is in regard to this point more particularly, that the greatest practical difference between the emetic tartar and bloodletting consists. By the latter measure we almost always obtain a diminution of the fever, of the oppression and the bloody expectoration, so as to lead both the patient and attendants to believe that recovery is about to take place: after a few hours, however, the unfavourable symptoms return with fresh vigour, and the same scene is renewed, often five or six times, after as many successive venesections. On the other hand, I can state that I have never witnessed these renewed attacks under the use of tartar-emetic. In these cases we observe only in the progress towards convalescence, occasional stoppages. And this is more particularly the case in respect of the stethoscopic signs; as we find that between the period when the patient experiences a return of his appetite and strength, and fancies himself quite cured, and the period at which the stethoscope ceases to give any indication of pulmonary engorgement,—more time frequently elapses than between the invasion of the disease and the beginning of the convalescence. It is necessary to observe, however, that this remark is still more frequently applicable to the disease when treated by bloodletting; and moreover, that the patients subjected to the antimonial

* See an interesting and valuable note by Dr. Forbes, in his translation of Laennec, third edit. p. 269. It contains a succinct history of the new mode of exhibiting tartar-emetic, and some very judicious comments upon it.

method never experience the long and excessive debility which too often accompanies the convalescence of those who had been treated by repeated venesections." (Dr. Forbes's Translation, p. 255.)

M. Peschier, of Geneva, appears to have given tartar-emetic much in the same way as Laennec; and with such success that, according to his report, he speedily cured almost every case without the aid of bloodletting, although he never exceeded fifteen grains in the twenty-four hours. (Biblioth. Univ. Juin, 1822.) Of those who have written favourably of the remedy on this side of the channel, we may name Dr. Mackintosh, of Edinburgh, and Drs. Graves and Stokes, of Dublin; but these physicians differ from its foreign advocates in making tartar-emetic a remedy secondary to bleeding. The experience of the former leads him to conclude that vomiting is more speedily produced by a small dose dissolved in a large quantity of water, than a large dose of the drug mixed with a little sugar; but in the latter case the nausea is more severe and of longer continuance than in the former. (Practice of Physic, vol. i. p. 426.) Drs. Graves and Stokes begin with a mixture containing six grains for the first twenty-four hours, and add to this two or three grains each day afterwards, as the severity of the case may require, until fifteen grains are given daily; beyond this quantity they think it unnecessary to go. They use general and local bleeding freely, and in case of an increase of the symptoms, resort to it without trusting to larger doses of the tartar-emetic. They consider the treatment by this medicine as most eligible in strong constitutions in the early stage of inflammation, during the prevalence of the crepitant rhonchus, and before there is any dulness on percussion; when hepatization has taken place, it loses much of its efficacy. Any symptom of gastritic disease they consider as counter-indicating its use; and they find that the *tolerance* of the remedy is sometimes more readily established by applying leeches to the epigastrium. (Dub. Hosp. Rep. vol. v.)

Our own experience in the use of tartar-emetic leads us to agree pretty closely with these observations. In truly sthenic cases of pneumonia, we have generally found that it perpetuates the impression produced by the lancet more promptly and decidedly than any other remedy, and in a proportionate degree ensures the relief of the patient, at a smaller expense of blood and strength than the ordinary method of treatment, even with the aid of mercury. But we cannot assent to the opinion of Rasori, in which Laennec seems to join, that the remedy has no depressing effect except in regard to the inflammation, which it directly reduces; for we have very commonly found that it lowers the strength, and sometimes the frequency of the pulse, before its beneficial effects on the inflammation are perceptible, and occasionally even when these do not ensue. It may have specific effects on the inflamed vessels, but it likewise sometimes exerts a sedative action on the general circulation. This is not always apparent, and its absence may result sometimes from the local irritation of the medicine counteracting its depressing influence, and in some cases from the system being capable of resisting its effects. Certain it is, that in a few instances, principally in children, its administration has been followed by a more rapid sinking, and seemed to hasten the fatal termination. These were, it is true, cases of advanced disease, in which, after death, the lungs exhibited extensive marks of unconquered inflammation. We think it more necessary to point out this depressing operation of tartar-emetic, because Laennec takes no account of it, but considers cases of debility as particularly adapted for its use. Nevertheless we have seen aggravated instances of pneumonia advanced to the second, if not the third stage, and accompanied with great apparent exhaustion, recover under the influence of tartar-emetic and blisters, when bloodletting had ceased to bring relief and was no longer practicable. Unless, however, in case of failure of the action of other remedies, we should not be disposed to give tartar-emetic in any case where the circulation is really weak; and it should likewise be withheld where it appears to depress greatly without improving the state of the respiration.

A very important point in the exhibition of this medicine is to establish the *tolerance*, which means an insusceptibility of the stomach and bowels to its emetic and purgative effects. Rasori supposed that the presence of an inflammation in the system is the cause of the drug having a different operation from usual, and that the stimulus of this inflammation must be neutralized by the directly sedative or *contro-stimulant* property of the medicine before the body can be made sensible of its common emetic effects. But, as Laennec has observed, this is not consistent with the fact, that after the tolerance is once established, ten, twenty, or thirty grains may be taken and continued daily throughout the period of convalescence without any sensible effects. We have seen patients recover their strength, appetite, and power of digestion when they were taking twelve grains daily. The experience which we have that the most inflammatory and plethoric cases are those in which this medicine is most successful, indicates indeed its peculiar power over excited vascular action, but its occasional utility over more advanced forms of pneumonia and in hernia humoralis proves that it likewise possesses a sorbefacient power. (See Dr. Mackintosh's Experiments, Lancet, vol. ii. p. 536.) The directions which we have quoted from Laennec with regard to the best mode of exhibition to ensure the tolerance of the medicine, are those which we have generally found most successful. It is desirable to vary the vehicle according to the taste of the patient, and to choose that which is most grateful to his stomach. We have often found the "king's cup," a weak infusion of fresh lemon-peel sweetened according to the liking of the patient, convey the medicine very comfortably, but it is best not to give more than a wine-glassful with each dose, as in our experience a larger quantity is more apt to produce vomiting. The first dose generally produces this effect however given, and frequently the second more slightly; the third commonly merely nauseates, and the tolerance is then established. This is the common average of the operation of the medicine. If the vomiting continue after the second dose, or be very violent then, i

will be expedient to take some measures to diminish the irritability of the stomach and bowels. Where there is a diarrhœa as well as vomiting, instead of the syrup of poppies recommended by Laennec, we prefer the addition of three or four drops of the liquor opii sedativus, or of the solution of muriate of morphia, to each dose of the medicine, and this may be advantageously given with an effervescing mixture, as recommended by Dr. Tweedie in the article Fever; but it is necessary that the alkaline carbonate should be accurately neutralized, otherwise it would decompose the tartarized antimony. Where the vomiting becomes obstinate and urgent, we can confidently recommend the addition of a drop or two of hydrocyanic acid to each dose of the medicine, as in the following form:

R. Antimon. tart. gr. iss. ad gr. iiss.
Aquæ destill. f.℥i.
Acid. hydrocyan. *mi*.
Aq. cinnamomi, (vel flor. aurant.) f.℥iii.
Syrup. tolutan. f.℥i. Fiat haustus.

This may be given every second, third, fourth, or sixth hour, according to the severity of the case. The draughts should not be made long before they are used, as they soon become decomposed, and the oxide of antimony is precipitated. For this reason it may be sometimes useful to prescribe the tartarized antimony in a powder, to be dissolved at the time of exhibition in a wine-glassful of lemon-peel infusion, to which, if necessary, the hydrocyanic acid may be added. We decidedly prefer the exhibition of the medicine in a liquid form to that of a powder, as we consider it to be more safe and efficacious. Where, notwithstanding the combinations just mentioned, the vomiting still continues, a few leeches to the epigastrium, or, what is more efficacious, a mustard poultice applied there for a few minutes, will sometimes effect the tolerance of the remedy. If, notwithstanding all these precautions, the vomiting persists, it must be left to the discretion of the practitioner whether the medicine is to be continued or not; and in deciding this he will have to balance between the beneficial influence already produced by it, and the distress and injury likely to ensue from so violent an operation still continued.

It seldom happens, however, that this intolerance of the medicine does remain where its continued exhibition would be safe; and unless the remedy should be producing a marked improvement in the pulmonary symptoms, we may generally consider obstinate and violent vomiting or diarrhœa as an indication to desist from its continuance. We are further warned from its use in all cases where there is a florid red, or brown and parched state of the tongue, with great thirst, and tenderness and tension in the epigastrium, or over the whole abdomen. We do not find that a moist furred tongue, whether white or brown, gives any contra-indication, and we have often seen this state removed by the first operation of the medicine. In continuing the medicine we must be guided more by the physical than by the general signs of the disease; and it should not be hastily discontinued, for it does not appear, like mercury, to produce a permanent effect on the system. As long as there is a rusty tinge and viscidity in the sputa, and distinct crepitation, or absence of the respiratory sound in the seat of disease, the medicine should be continued, three times a-day at least. It is an advantage of this remedy that it may be combined with others, adapted to the various stages of the disease; and, although such combinations speak equivocally as to its individual powers, in some of the severest cases in which the treatment was most signally successful, we have joined the tartar-emetic with general bloodletting at first, with blistering and mercury afterwards, and lastly with the decoction of senega or some slight tonic.

Mercury and opium.—The exhibition of these drugs as an antiphlogistic remedy, first practised by Dr. Robert Hamilton, (Medical Commentaries, vol. ix. p. 191,) and afterwards revived and warmly recommended by Dr. Armstrong, (Practical Illustrations of Typhous Fever, &c. p. 453,) is now pretty generally resorted to in this country, and as it has been fully noticed in several preceding articles, need not here long occupy our attention. Like tartar-emetic, it is to be generally considered only as a measure secondary to bloodletting, and the salutary effect is particularly shown when the latter remedy has reduced the inflammatory orgasm, and can be carried no further. The efficacy of this combination depends in a great measure on its being given to such an extent as to affect the gums; but its beneficial operation is often manifest before this effect is produced, and in some cases, especially in children, without its occurring at all. But there is seldom that obvious improvement from the first doses which is often apparent in the exhibition of tartar-emetic; the operation of mercury is more gradual, and, as may be expected, when once the system is under its influence the effect is more permanent. It is therefore especially adapted to the advanced stages of the disease in which the continued operation of a remedy is required to resolve a solidification of the lung; and in effecting this, and in preventing those remains of inflammation which lay the foundation for destructive chronic disease, mercury is pre-eminently serviceable. Some doubt has existed whether the mercury or the opium is the principal agent in subduing inflammation. Dr. Hamilton considered it to be the calomel, and he combined opium with it to relieve pain, and to prevent it from passing off by the bowels. Dr. Armstrong held that the opium was a powerful means of subduing inflammation after bleeding had made a decided impression on the general vascular action. In pneumonic inflammation, however, we cannot but admit that both medicines have their beneficial effects each by its own influence, and by modifying the action of the other. Thus the opium acts as an anodyne in subduing the pain and cough, and as a sedative in relieving that nervous irritation which often follows both bleeding and the free use of mercury, and which tends to the re-establishment of inflammation; whilst the injurious stimulant and restringent operation of the drug is prevented by the previous bloodletting and the mercury. The latter medicine, again, besides this corrigent effect, more gradually exerts that specific antiphlogistic and sorbefacient action which has established its value in many diseases, and of

which the treatment of iritis frequently affords a visible illustration. If we adopt this view as a guide in the application and management of these combinations, we shall find that it leads to the rules which experience has already sanctioned.

Calomel is the form of mercury which is generally preferred in acute inflammations, and as its purgative effect is not an object, there is the greater need to combine it with opium. Dr. Armstrong, indeed, considered the purgative operation of a first full dose of calomel to be salutary, by brushing away the coat of mucus from the intestines, and thus opening the absorbents for the specific action of the medicine: this may with advantage be practised in pneumonia, and especially where a disordered or torpid state of the excretions indicates a purgative. With this view, from five grains to a scruple of calomel may be given immediately after the first bleeding; but as a continued catharsis is seldom desirable, especially where there is free expectoration, the opium should be added to the subsequent doses. With respect to the quantity and frequency of these, some difference must be observed according to the form of the disease. In the most sthenic cases uncomplicated with idiopathic fever or gastric affection, large doses of calomel, of from six to twelve grains, or even more, may be given three or four times a-day with better effect than smaller doses more frequently repeated. The proportion of opium must likewise be varied according to circumstances. Where after a full bleeding the pain is considerable, with little fulness in the pulse, and especially if there are signs of nervous irritation, from a grain to a grain and a half of opium may be added to every six grains of calomel; but if the action of the heart is still strong, half or a third of that quantity will generally be sufficient to prevent the mercury from irritating the bowels, which is in that case the principal object of the opium. We have generally preferred Dover's powder, or a simple combination with ipecacuanha to the opium alone; for while the anodyne powers of the drug are not impaired, its stimulant quality is thus considerably diminished. In a few instances the sulphate of morphia has been substituted for the opium, and apparently with good effect, but our experience on this point is too limited to enable us to speak with certainty. In less sthenic cases, and especially where there is much gastric derangement, or a fever which assumes more of the idiopathic character, with a dry loaded tongue, hot skin, and vitiated excretions, the calomel is with greater advantage given in more divided doses, and frequently; as from gr. iss. to gr. iii., with two or three grains of Dover's powder every second or third hour. In some instances, particularly where there is an irritative diarrhœa, the hydrargyrum cum cretâ may be advantageously substituted for the calomel, double the quantity being generally given. The remedy, in whichever of these various ways it is given, should be continued until it either produces a decided impression on the disease, or affects the gums. Generally these effects take place simultaneously, and the improvement is seldom permanent and progressive until the influence of the mercury on the system is manifest in the gums. It is a favourable sign when this takes place readily, for the most obstinate and formidable inflammations counteract the specific influence of mercury; and if, after salivation has been produced, the inflammation becomes rekindled, the gums get well, and the breath loses its mercurial fetor. As soon as the mercury has shown decided effects, it may be diminished to two or three moderate doses in the day; but when the disease has advanced to hepatization, it is proper to keep up its influence in a minor degree for some days. Mercurial inunction is sometimes practised to accelerate the introduction of the metal into the system, but this is too slow a process to be of material assistance where so much promptitude is required.

[Opium alone, or in the form of morphia or other of its preparations, the writer has found a most valuable remedy in active pneumonia after bloodletting; and in asthenic cases where bloodletting has not been indicated. In such cases, it must be given in full doses. The objections, urged against its use in this and other inflammatory affections, have been canvassed elsewhere (See Narcotics). To its value in pneumonia other observers have equally deposed. (Christison, *Dispensatory*, p. 684, Edinburgh, 1842. See also, art. *Pneumonia*, in *Encyclopäd. Wörterb. der Medicinisch. Wissensch.* xxvii.712, Berlin, 1842.]

Counter-irritants. — It is generally agreed, among medical writers, that blisters are not admissible in the early stage of pneumonia, and not a few deny their utility altogether in the acute disease. There are two objections against their use: one is, that whilst the inflammatory fever lasts, the stimulus adds to it, and thus reacts injuriously on the inflammation; and the other, in our estimation scarcely less important, that they prevent the use of those means of examination of the chest, which, as we have seen, are necessary to inform us accurately of the state of the pulmonary disease, and of the effect of more powerful remedies upon it. The last objection does not apply to blisters on the legs or some distant part, which are recommended by some physicians even in the early stage. M. Lerminier applies two to the legs immediately after the first bleeding; as soon as they are dry, he repeats them on the thighs, and does not use them on the chest until the disease has taken on a perfectly chronic character. Unless, however, in case of complications with cerebral disease, in which distant revulsion may prove salutary, the effect of this measure is too trivial to be relied on, and the practitioners of this country seldom trust to counter-irritation on any other part than the parietes of the chest, but reserve its application till the active character of the disease has been subdued by other measures. In slight cases they may often be advantageously applied immediately after the first bleeding; but in the severer disease both the objections which we have just stated would deter us from using them until the pulse is soft, and the heat of the skin moderate. Whilst the disease remains acute, blisters from six to ten inches square are to be preferred to smaller ones, as they scarcely irritate more, and their salutary derivative and evacuant effect is much greater. When the disease, after having reached the stage of hepatization, is proceeding towards cure, smaller

blisters, repeated one after another in different parts of the chest, are of considerable utility, and enable the patient to bear a slightly tonic treatment, which is often very salutary at this period. It is at this time only that other means of counter-irritation can well be substituted for blisters. The friction necessary for the application of the tartar-emetic ointment or solution constitutes an objection to its use during the pain, cough, and oppression of the acute stage; but as a safeguard against relapse, and as a means of countervailing the internal irritation and of promoting the sanative process, this method of counter-irritation reaches deeper and is more permanent than repeated blistering. (See COUNTER-IRRITATION.) Rubefacient plasters, as those containing a small proportion only of cantharides, are sometimes sufficient, and produce considerable benefit on the same principle; but they should be of full size, and renewed with sufficient frequency to insure their continued activity.

Evacuants.—We may comprehend, under this title, emetics, purgatives, diuretics, and diaphoretics, all of which are occasionally useful, but it is generally agreed that they are remedies of minor importance, and require some judgment in their application. From the success which has attended the treatment of pneumonia by emetics, in the hands of some physicians, as Stoll, Riverius, Dumangin, Hellis, and Good, we cannot doubt that these remedies are sometimes decidedly useful; and probably they may be so, in the early stage of the disease, by breaking that chain of morbid action by which the incipient congestion becomes converted into inflammatory fever, as well as by their relaxing and derivative effect. They are, however, generally considered as violent and uncertain remedies, and enough of their peculiar effect may be obtained in the ordinary operation of the large doses of tartar-emetic, of which the ulterior action has a higher claim to our confidence.

Much difference of opinion exists as to the employment of purgatives in pneumonia; some practitioners, particularly those of this country, using them freely, not merely to evacuate the bowels, but also as depletories to reduce the action of the heart and arteries. Dr. Pring recommends them with this view, and considers them of equal power with bloodletting in subverting inflammatory action. (Principles of Pathology, p. 208.) The general objection against their use is, that they tend to check the expectoration, which is a natural means of relief to the disease; but probably they are likewise injurious in exciting in the mucous membrane of the alimentary canal an inflammatory state, which gives to the disease that typhoid tendency in which we have recognised one of its most dangerous forms. These considerations deter us from exciting any thing like a continued discharge from the intestines, but we consider that their daily evacuation is a safe and expedient measure, and if this is not effected by the medicines given with another object, it must be excited by a colocynth pill or senna draught, or, where there are signs of gastric excitement, by castor oil or a laxative enema.

Diuretics are indicated chiefly where there is a simultaneous effusion into the pleura; but we have likewise found them useful in combination with tonics in the decline of the disease, to remove the œdema which commonly lingers in the lungs and sometimes affects other parts of the body after the active inflammation has subsided. Nitre, in doses of a scruple or half a drachm in the former case, and the same, or the spirit of nitric ether in the latter, generally answer as well as any other medicine, and their effect is commonly increased by the mercury, digitalis, squill, or other medicines given to fulfil other indications. A diaphoretic operation also often results from the use of the tartar-emetic or calomel and opium when these are given; when they are not, a great heat of skin often renders it expedient to give James's powder, or antimonial or ipecacuanha wine, with a view to determine to the skin; and in children especially, the warm bath sometimes proves useful in the same way; but these remedies are too uncertain and trivial in such a disease as pneumonia to withdraw our principal trust from other more important measures. In some cases, profuse sweats come on, which weaken the patient without relieving the symptoms, and require the exhibition of a mineral acid to restrain them.

Sedatives.—The remedies of this kind which have been held in greatest repute in pneumonia are opium and digitalis. We have already noticed the former in conjunction with calomel, but it is likewise employed alone with a view to quiet vascular action. Dr. Armstrong recommends at least three grains of opium to be given immediately after bleeding to syncope or approaching syncope, and its effect is to preserve the reduction which the loss of blood has already effected in the pulse. This is a point particularly to be observed in the administration of opium. As long as the vascular action is strong, this drug will stimulate and prove injurious; but when reduced by a full depletion, it seems to paralyse those powers of reaction by which, after this temporary reduction, irritation and inflammation are rekindled. We have repeatedly seen the utility of opium in this way; but it has been generally in the first stage of the inflammation; and although we do not hesitate to give it in the full dose recommended, we judge it to be always safer to combine it with calomel and ipecacuanha. Where there is much pain, from twenty to forty minims of the liquor opii sedativus, given immediately after the bleeding, act more speedily and satisfactorily than solid opium. In the after-stages, when the antiphlogistic remedies have reduced, as far as may be, the inflammatory action, opium often proves of the greatest benefit in relieving the cough, which frequently continues troublesome and obstinate, even in the decline of the disease. With this view it is generally combined with expectorants, which we shall presently have occasion to notice. Hyoscyamus, conium, extract of lettuce and of belladonna, are sometimes used with the same intention, and, where opium is ill borne, may prove serviceable; but, although they may at all times be given with less risk, they are generally much inferior to it in efficacy. These medicines, besides reducing the excess of irritability on which the act of coughing depends, seem in some degree likewise to relieve the oppressed state of the breathing, which occasionally remains after the

active disease is subdued, and this they probably effect by diminishing those changes in the blood by which it is rendered venous, and thereby lightening the task of the function of the lungs. (See Dyspnœa. The action of digitalis is considerably different, being principally on the vascular system, and it does not possess any anodyne qualities. It has been much extolled as an aid to bloodletting in reducing inflammatory action; but although it occasionally shows considerable efficacy, its operation is far too uncertain to entitle it to our confidence. Its exhibition is moreover not unattended with danger, for when given largely to affect the pulse, it sometimes develops its effects suddenly in syncope and extreme reduction of the heart's action. We trust to it more in the decline of the disease; and in the dose of ten to twenty minims three times a day, combined with an opiate in an expectorant mixture, we have found it of great use in reducing the pulse and easing the respiration. Some practitioners speak highly of larger doses, frequently repeated, until an impression is produced on the circulation: but we have not seen enough advantage in this plan to induce us to recommend it, and unless watched with the closest attention, we cannot consider it a safe practice. Colchicum may be used with the same intention, but it is more apt to pass off by the bowels, and should therefore be combined with opium. It is most suited to the pneumonia of rheumatic and arthritic subjects, and may be given in the dose of ʒi of the wine with a few grains of carbonated alkali. Hydrocyanic acid does not appear to deserve the encomiums that have been passed upon it, and except to quiet an irritable state of the stomach, we have not seen it useful in pneumonia.

Expectorants.—During the active stage of the inflammation, whilst the pulse is sharp and the skin hot, the secretion of the bronchial membrane is not within the influence of any of those medicines which are called expectorant. The general measures which reduce the inflammatory orgasm of the great pulmonary vessels are then the best means of relaxing those of the bronchi, and this effect may afterwards be kept up by small doses of antimony or ipecacuanha. In an advanced state of the disease, however, the promotion of expectoration becomes an object of great importance, as on its accomplishment may depend the life of the individual. Where the inflammatory symptoms have entirely given place to those of weakness with a great embarrassment of the breathing, the carbonate of ammonia becomes a most valuable remedy, and we have more than once seen it apparently turn the scale in imminent cases. It may be given in doses of five grains or more every hour or every two hours, or more frequently if the sinking state of the patient seem to require it. The decoction of senega is in these cases a good vehicle for it, and great advantage has sometimes resulted from the addition of the tincture of the *lobelia inflata*, which, although an uncertain remedy, often shows great powers in facilitating expectoration and relieving dyspnœa in several advanced forms of pulmonary disease. The first dose of the medicine should not exceed ten minims; but unless it produces sickness, it may be increased by three or four minims in each successive dose. Different individuals bear it very variously: we have known a drachm taken at a dose, with great relief to the breathing, and without inconvenience; in another instance eight minims produced such sickness and giddiness that it became necessary to discontinue its use. When the urgency of the symptoms which indicated the use of ammonia has ceased, it may be of importance to keep up a free secretion from the bronchi, in order to assist in the resolution and dispersion of the solid effusion in the tissue of the lungs, and for this purpose expectorants of less stimulating quality are to be preferred. We have generally found a combination of tincture of squills and ipecacuanha, in the dose of ten minims of each, answer very well; if the cough is troublesome, a few drops of liquor opii sed. or forty or more of the compound camphor tincture should be added. The vehicle for these medicines may be the almond emulsion, with a little liquor ammon. acetat. when the expectoration is thin and scanty; but when it continues viscid, we have found great benefit result from the exhibition of expectorants in an alkaline vehicle, which is the only form in which the alkali treatment, so much extolled by Sarcone and Mascagni, has appeared to us useful in peripneumony. Ten or twenty minims of liquor potassæ, or the same number of grains of carbonated alkali, may be given with the above-named expectorants in water, camphor julep, or any simple vehicle, or in the more asthenic cases, with decoction of senega. In the course of recovery from pneumonia we often find it useful, whilst any pulmonary symptoms remain, to join some expectorant with the tonic that is employed.

[There is no class of remedies more uncertain in their action than expectorants, and certainly none that require more caution as regards their administration in pneumonia. Let it be borne in mind, that there is no article in the Materia Medica, which is an expectorant under all circumstances. Expectorants are altogether indirect agents; hence we find an expectorant effect equally from depletives and from tonics and excitants; from narcotics and from counter-irritants; from nauseants and from emetics. (See Expectorants.)]

Tonics and stimulants.—In ordinary pneumonia this class of medicines is out of the question as long as any signs of active inflammation remain. When, however, depletions do no further good, and the pulse is weak, the skin cool, and the expectoration no longer rusty and tenacious, then, although some dyspnœa and cough still remain, considerable benefit is sometimes derived from the exhibition of a mild vegetable tonic, such as the decoction of senega, or a weak infusion of calumba. We have already named the first of these as a vehicle for carbonate of ammonia to promote expectoration, but it seems also to prove useful from its slightly tonic property, and as a stimulant to the absorbent system. In the state which we have just described, we have often seen the symptoms remaining stationary, without tendency to improvement, until this medicine was given, and then in a few hours the pulse has become slower, the breathing more free, the tongue cleaner, and the strength somewhat improved.

By auscultation, also, we have found in a returning crepitant rhonchus or other vesicular sound, a proof of the impulse which this treatment gives to the absorption of the effused matter. When the active stage of the inflammation has been subdued by tartar-emetic, it is a good plan to continue to give it three or four times a-day in this decoction, as there is nothing inconsistent in the action of the two medicines. After the mercurial treatment it is even more useful, and may generally be given soon after the gums are decidedly affected. The infusion of calumba we have thought better adapted to cases in which there had been much accompanying gastric disorder, and in these it has sometimes cleansed the tongue, which had continued foul in spite of the prevalence of mercurial action in the system. In the exhibition of either of these tonics, however, a close attention must be paid to prevent the re-kindling of the inflammatory disease, and they must be discontinued on the appearance of any sign of reaction. They are most safely employed in conjunction with an external counter-irritation on the chest; and it is under these combined measures that the most rapid recoveries take place. In the more typhoid forms of the disease, especially those complicated with adynamic fever from the beginning, tonics and even stimulants are required more frequently, and with less limitation. In some of these cases, where bloodletting is not borne, bark and camphor may be given even in the early stages of the disease, for the pneumonic affection is really more a passive congestion arising from an extremely atonic state of the vascular system, with probably an altered state of the blood, than a true inflammation. Laennec says that he has, with success, given both bark and wine in certain epidemic peripneumonies, particularly in one which prevailed among the troops in 1814. He also recommends these to be administered towards the termination of the disease in old persons, and in debilitated and cachectic subjects, when, after the suppurative stage, the fever passes off and resolution goes on very slowly. He considers cinchona the best remedy in gangrene of the lungs, even when there is extensive hepatization around the eschar; but to be effectual it must be given to the extent of an ounce of the powder daily, or an equivalent portion of sulphate of quinine. Except in case of complication with intermittent fever, where the specific operation of bark is required, we are disposed to trust at first to opium, camphor, and ammonia, in the typhoid pneumonia, combining them with calomel, and to resort to the bark only if the general strength seems to require it afterwards.

Application of the Treatment.—We have only to point out here the manner in which the several remedies which we have described may be combined in the treatment of individual cases. Where the case is at all severe, the treatment with tartar-emetic, or with calomel and opium, should be commenced immediately after the first bleeding, and continued uninterruptedly until an impression shall have been produced on the disease. It is not safe, however, with either of these remedies to lay aside bloodletting; if sensible relief does not ensue in the course of five or six hours after the first full bleeding, this measure must be repeated as before recommended. In the most acute and inflammatory cases, uncomplicated with gastric disease, we have sometimes combined the mercurial with the antimonial treatment, by giving a pill containing from six to ten grains of calomel, with from half a grain to a grain and a half of opium every four or six hours, and the tarter-emetic draught before prescribed, in the middle of that interval; and where the tolerance is established soon, the effect of this treatment is very powerful. If the bowels are too much acted on, the hydrargyrum cum cretâ in double quantity may be substituted for the calomel. When an amelioration takes place in the symptoms, the mercury may be omitted, and the case left to the tartar-emetic, and whatever depletion or counter-irritation may be required. If the attack of pneumonia is very recent, and accompanied with a sharp stitch in the side, or catch in the breathing, a full dose of opium immediately after a large bleeding, as recommended by Dr. Armstrong, will sometimes be found sufficient to cut short the disease. This plan can only be adopted where the bleeding has been so copious as to produce a great and real impression on the heart's action, almost, if not quite, amounting to syncope. The dose of opium should be large; three or four grains of the aqueous extract, or if the pain and tendency to reaction are urgent, from 30 to 60 minims of the liquor opii sed., are the preparations to which we give the preference. Even in this case we think it advisable to give from six to twelve grains of calomel, or from ten to twenty grains of blue pill, with, or soon after, the opium; the mercury does not interfere with the sedative operation of the latter, and by preserving the balance of the secretions, it prevents those functional derangements which sometimes follow the use of opium even in this way. If the disease has in any degree passed into the second stage, and even if the first has lasted more than twenty-four hours, there can be little hope of stifling it with opium, and we must then resort to the alterative powers of tartar-emetic or mercury, with whatever bloodletting the case may bear. Blisters can seldom with advantage be resorted to, until all fulness and hardness of the pulse and heat of skin have subsided; and either these symptoms, or even the continuance of a fixed pain, would counter-indicate the use of the decoction of senega, or any of the mild tonics which prove useful in the decline of the inflammation.

If, from the copious expectoration of pus and the physical signs of a cavity in the lungs, it is probable that an abscess has been formed, it may be necessary to support the strength by a stronger tonic, as the sulphate of quinine or bark with a mineral acid; but the expediency of this must depend on a complete predominance of the symptoms of weakness over those of inflammation. In case of gangrene, some of the medicines of a supposed antiseptic power may be given. Drs. Graves and Stokes, in a case of this kind, gave the chloride of lime in the dose of three grains with one of opium three times a-day, with the effect of removing the fetor from the expectoration, and for a time improving the symptoms. We have seen the same medicine in solution apparently produce

the same result; but we cannot expect much from the operation of such agents. The principal object in case of gangrene is to support the general strength, and counteract the noxious influence of the dead matter, until it can be thrown off from the system.

The great fatality of pneumonia among children renders it necessary that its treatment should be directed with the greatest care and promptitude. This fatality does not arise so much from the course of the inflammation, as we have seen that this is less rapid than in adults; but from the latency of the local symptoms, and the tendency of the disease, under this disguised form, to pass the period in which bloodletting is most effectual. Hence, many of the cases of infantile pneumonia which we have to treat, especially in the lower classes, are already in a sinking state; the depressing influence of the injured function of the lungs, which at this age ill bears any abridgment, having already removed the sthenic character of the disease. This circumstance represents to the mind the importance of physical examination of the chest in all the febrile diseases of children, in order that, if any crepitant rhonchus be discovered, the fit remedies may be promptly applied. In this early stage bloodletting is highly efficacious, but when used after the disease has lasted for several days, it sometimes produces convulsions and sinking, without relieving the respiration. The same observation may in some degree be applied to tartar-emetic, and yet these are the most effectual remedies which we possess for infantile pneumonia, and if used together at the commencement, seldom fail to subdue it. Mercury with difficulty produces its specific action on infants, but it is still of great effect as a purgative; and when bloodletting is no longer borne, calomel, in doses of half a grain up to two grains, according to the age of the child, every hour or second hour, is the remedy on which we have principally to depend. Unless where there is an irritative diarrhœa, opium can seldom be used with advantage; in that excepted case, Dover's powder is the best form. Although mucous or bloody stools imply an undue irritation from the calomel, and ought to be checked, yet copious evacuations of green bile are essential to the success of its operation, and seldom produce in the pneumonia of children the bad effects which result from purgation in the adult. It would seem that expectoration, as it is a less natural process in early life, so its importance as a vicarious discharge is of inferior moment, and does not prohibit purgatives and other measures that may arrest it. Counter-irritation with tartar-emetic ointment or solution is of great efficacy in the after stages of pulmonary inflammation in children, and should especially be persevered in where there is any sign of a phthisical tendency. This, together with a sedative linctus to quiet the cough, and a light tonic if required, constitute the chief part of the treatment most eligible in the decline of the disease.

In aged persons the disease is often very intractable, in consequence of the great debility which accompanies it. The mere circumstance of age should not, however, restrain us from the use of the lancet, where the state of the breathing and pulse, and heat of skin seem to indicate it. Frank bled an octogenarian pneumonic patient nine times with a happy effect. It must be confessed, however, that the period in which bleeding is useful in old people is short, and the frequent complication of a pituitous catarrh with pneumonia still further restricts its utility. Expectoration is in these cases a most important process, and when bleeding weakens so much as to be likely to interfere with the performance of this act, it must be abandoned. In some cases cupping may be substituted, but blisters of ample size are more effectual, and may be employed much earlier than in younger subjects. The internal remedies may be administered as usual, but it is often necessary to resort soon to the tonics and stimulants before described.

We know of no reason why the sex of the subject should materially modify the treatment of pneumonia. The presence of the catamenia ought never, in cases of any severity, to interfere with free depletory measures, for the influence of this relief on the system is trifling, compared with the progress of a dangerous inflammation. The case may be different in slight examples and towards the decline of the disease, and stimulating pediluvia may be used, if the circumstances indicate it, to promote a natural crisis of this sort.

The complications of pneumonia with other diseases will require that the treatment should in some measure combine the indications of these various affections. Thus in the complication with bronchitis the power of bloodletting will be more contracted, whilst the antimonial treatment of blistering will claim more confidence. In pleuropneumonia, local bleeding, in addition to venesection, becomes a very useful remedy, and if the pleuritic affection be extensive, or accompanied by much pain, calomel and opium will form the most eligible remedy. In the treatment of pneumonia occurring in continued fever, [and in all forms of typhoid pneumonia,] the probable duration of the latter affection must be held in view, and depletions practised in a more cautious manner. The mercurial treatment is generally the best here likewise, especially if the fever partakes much of the gastritic character; and the hydrarg. cum cretâ, with ipecacuanha or Dover's powder, is the preferable preparation. When any of these fevers take on the typhoid or adynamic form, stimulants and tonics will sometimes be required, and must be given, notwithstanding the pulmonary disease. It must be confessed that medicine has often very little power in these cases; but as far as our experience goes, stimulants judiciously given when the heart's action is very feeble, and the muscular powers are very low, have appeared to relieve the pulmonary affection, as well as for a time to restore a portion of strength; and it is only by overstimulating the heart that there is a risk of aggravating the inflammatory disorder. They must therefore be carefully watched, and diminished or withdrawn as soon as any sharpness or hardness is perceptible in the pulse. Besides those before enumerated, we may mention musk, which is highly recommended in the typhoid form of pneumonia by M. Recamier, who gives it in doses of from 24 to 30 grains, with an effect which he considers almost specific. It seems to us ques

tionable, whether the affections which have been called intermittent peripneumonies, and said to have been cured by bark, are really inflammations: it is more probable that they consist in a simple congestion of the lung, determined by the febrile paroxysms, just as simple congestions are more familiarly known to take place in the spleen, liver, &c.; and from the near pathological affinity between the two, it is not surprising that such a congestive state should produce many of the local phenomena of pneumonia. Although there can be no doubt of the power of bark and arsenic over these intermittent diseases, yet even here the oppression of the affected organ during the paroxysm is occasionally such as to require the aid of bloodletting. Neither should this measure be withheld, from fear of suppressing the eruption, in the pulmonic affections coming on at the commencement of the exanthemata: the internal affection is a present and dangerous evil, not to be neglected on account of other imaginary ones.

In the peripneumonies supervening on hooping-cough and influenza, it is sometimes a chief indication to give sedatives to allay the cough, which appears often to have a considerable share in producing the parenchymatous inflammation. Besides bleeding, therefore, to the extent that the case may require, large doses of the tincture of hyoscyamus (℥ss, and upwards, or, in hooping-cough, the extract of belladonna, in doses of half a grain to the adult, and one-sixteenth to children below two years, these being gradually increased) will be found of much efficacy in counteracting the inflammatory tendency of these affections. Local depletions and counter-irritation will generally be sufficient to arrest the inflammations intercurrent on phthisis; and we have found the tincture of digitalis very useful in these cases. Where an inflammatory state of the mucous or serous membranes of the alimentary canal accompanies pneumonia, it is of great moment that the treatment should extend to these complications, for they greatly aggravate the case, and render it less tractable. Free leeching of the abdomen must be included in the depletory measures, and the hydrargyrum cum cretâ, with Dover's powder, will be the best antiphlogistic alterative. Purgatives must be at first rigidly proscribed, and the bowels merely evacuated by laxative enemata or suppositories. In the progress of recovery, a teaspoonful of castor oil daily, and infusion of calumba with dilute nitric acid, or some such light tonic, will often contribute greatly to restore the healthy functions of the membrane.

Diet and Regimen.—No one can question the propriety of a strictly antiphlogistic regimen in ordinary cases of pneumonia. A total abstinence from all solids must be enjoined during the inflammatory stages of the disease, and the liquids taken should be of the mild mucilaginous kind, such as barley-water, tea, lemon-peel, and other simple vegetable infusions. It is generally recommended to give these beverages warm: but unless large draughts are taken, we see no objection to their being given cold if the patient prefers it. We have heard Professor Hamilton of Edinburgh express his decided belief that liquids are injurious in pneumonia by adding to the mass of blood, and thus counteracting a principal good effect of bleeding; and so far does he carry this opinion, that he considers that even pediluvia may do harm by throwing more liquid into the system through the absorbents. Although a zealous advocate for a dry diet in some other complaints, the writer is not persuaded of its utility in the present disease, except in cases where the dyspnœa is urgent. In such cases we have seen the breathing distinctly become worse after copious draughts of liquid, and with a view to keep the mass of blood which passes through the lungs as rich in quality and as small in quantity as possible, a paucity of drink may here be reasonably recommended. The antimonial treatment generally requires a certain degree of abstinence from liquids; for until the tolerance is completely established, a large draught is almost sure to produce vomiting. M. Chomel has pointed out a very important exception to the utility of an absolutely antiphlogistic regimen, in the case of those addicted to excess in wine or spirits. The great fatality of pneumonia in these subjects when treated in the usual way is well known; and observing that one man accustomed to such excess, who continued to take a pint and a half of wine daily throughout his illness, speedily recovered from the disease after only one bleeding, M. Chomel afterwards prescribed a certain quantity of wine in similar instances, and with a success that encouraged him strongly to recommend the practice. These may probably be included in the class of malignant cases, in which Laennec says that both wine and bark are beneficial. After the active stage of inflammation has been subdued, the moderate return to nourishing food, as the appetite craves it, is desirable. It should, however, be confined at first to farinaceous liquids, light puddings, and the weakest chicken or veal broth; these may be gradually improved in nutriment, and in the course of a few days a little white fish may be allowed; and the return to ordinary animal food made by degrees and with circumspection. In case of gangrene or extensive suppuration, as manifested by fetid or copious purulent expectoration, with great prostration of strength, a more nutritive diet, such as beef-tea and animal jellies, will be required; and these are cases in which wine may sometimes be cautiously administered; but too much attention cannot be paid to watch lest this regimen should re-excite an active state of inflammation.

In the progress of convalescence from pneumonia, we may say of nutritious food what we have remarked of tonics, that it must be watched in its effects, and that its tendency to rekindle the local disease may be safely restrained by the simultaneous use of counter-irritation on the chest.

Patients labouring under peripneumony should be kept in an airy room of moderate temperature, (about 60°,) being protected on the one hand from an accumulation of heated or impure air, and on the other from draughts of cold air. These points require the physician's attention, and are too important to be left to the sole discretion of the attendants. Much covering can seldom be borne, and it is therefore the more necessary to guard against the effects of accidental cold; whilst the oppressed state of the breathing still requires that the air should not be close or impure. It is

of some importance likewise, in the severer cases of inflammation of the lungs, that the chest should be raised above the level of the lower part of the body. The best method of doing this is by a bed chair, which by means of a notched rack can be raised to different angles with the level of the bed; but the same object may in a measure be attained by propping the back with pillows. This posture, besides that it facilitates the breathing and expectoration, prevents the gravitation of the blood to the lungs; and from the close connection which we have frequently noticed between the mechanical and the active hyperæmia of the lung, the importance of this last point is obvious. The exertion of the lungs required in talking is injurious, and must be avoided, and the bodily efforts should be confined to necessary acts. Muscular movement hurries the circulation, and that which does this in the disabled state of the lungs necessarily causes that injurious congestion in the organ which we have so frequently noticed in its connection with inflammation.

In enumerating the causes of pneumonia, we had to remark that nothing so strongly predisposes to the disease as its previous occurrence in the individual. Hence *prophylactic measures* become of great importance, and the more so in proportion as the attack has been frequently repeated. The necessity is obvious in such cases, of protection from the various exciting causes, by warm clothing, by avoiding exposure, exertions of the voice, and violent exercise of any kind, by abstaining from excess in diet, and by living on that quantity and quality of food which support the strength without inducing depletion, and by such diet and regulated exercise, or if necessary by proper medicines, ensuring the due performance of the secretory functions. Among the most essential articles of warm clothing, we may mention a flannel waistcoat next the skin, and during the prevalence of cold weather, a wash-leather vest over it: these will be found more effectual and less cumbersome than a larger quantity of outer clothing, and should never be neglected by the pulmonary invalid. We cannot inveigh too strongly against the pernicious practice of females liable to pulmonary inflammations subjecting themselves with their necks and chests bare to the trying changes of temperature inseparably attendant on evening visiting. In cases where, in spite of all precautions, the complaint recurs repeatedly at every return of cold weather, and renders the individual a constant invalid, a change of residence during the winter and spring months to a more genial climate becomes a desirable measure. Torquay and the Undercliff of the Isle of Wight in our own country, and the south-west of France, the coast of Egypt and Barbary, Madeira, and some of the West India Islands may be named as generally the most eligible places of resort; but the circumstances of the individual case must in great measure determine the choice. (See Climate.) The most efficacious remedial measures which we know of to counteract this tendency to the reproduction of pectoral inflammation, is a continued counter-irritation, by means of tartar-emetic, or a seton or issue, on the chest. We give the preference to the former; and we have seen patients under its influence regain a degree of robustness and hardiness which they had not known for months. When this measure seems to be no longer necessary, the mild irritation of a pitch plaster may be substituted. Those persons in whom there is only a proclivity without any symptoms of real disease, should habituate the pulmonary circulation to regulated impressions of cold and healthy reaction, by sponging the chest with vinegar or salt water, at first tepid, and afterwards cold, and using vigorous friction with a rough towel afterwards.

V. Chronic Peripneumony.

Laennec commences a section under this head, with a question as to the existence of such a disease; and although he adduces a few examples, which he admits to be of chronic inflammation, he views it as "hardly probable that an organ so vascular, so mobile, and so essentially living as the lungs, can remain long in such a state of slow and inactive inflammation, as we know to be the condition of organs less necessary to life." (De l'Auscult. Méd. t. i. p. 475.) But this argument is hardly tenable on a comparison with other organs equally vascular, and is inconsistent with the existence of chronic pneumonia to the extent in which he admits its existence. The form of disease considered by him to be chronic peripneumony is a hard compact kind of hepatization, sometimes found around gangrenous excavations and hæmoptoic engorgements, and very rarely also around tubercular cavities and between tubercles. The lung thus affected creaks when cut, is more livid or grey than ordinary hepatization, and presents a more distinctly granular form, so that it resembles the eggs of certain insects closely pressed together, without any intervening substance. This may reasonably be considered the chronic form of granular hepatization. But as we have found the acute disease occasion a consolidation of the lung without the appearance of granules, so it may be reasonable to expect that the chronic inflammation may present us with a corresponding uniform kind of induration. Accordingly, we find Andral, Chomel, and Louis, describing other non-granular forms of chronic solidification. It is sometimes found of a bright red or a buff colour, but more frequently it is livid or grey, being variously modified by the quantity of blood and the black pulmonary matter in it. It exudes little or no fluid when pressed, and is quite solid, sometimes approaching to cartilage in density. The red kind is most commonly a sequel of the acute disease imperfectly cured; the grey kind is more frequently found in the lungs of phthisical subjects with miliary tubercles scattered through it or surrounding tubercular vomicæ. The resemblance between the substance of this miliary tubercle and this grey uniform induration, and the circumstance that yellow tubercular matter is frequently found in the tissue thus indurated, led Laennec to the belief that this induration was only a diffused form of the same accidental tissue which he called a first stage of tubercle. The resemblance is certainly very strong, and as we often see an indurated hypertrophy of the interlobular septa, (See Dr. Hope's coloured illustrations, figs. 3 and 5,) so a close inspection will generally detect that the solid

state of the lung is owing to the same deposition in the interstitial tissue of a matter more or less dense, which we know in other parts to follow chronic inflammation. As far as it is connected with phthisical disease, this matter will be fully treated of under the head Tubercular Phthisis; but we cannot refrain from repeating the opinion (which is nearly that of Andral also,) that the miliary and diffused indurations considered by Laennec as the first stage of tubercle, are the effect of chronic inflammation of the interstitial tissues of the lung. The length to which this article has extended prevents us from entering on the question of the relation of inflammatory to consumptive disease; but we cannot refrain from expressing our belief, that if tubercle is not generally produced by chronic inflammation terminating in an irregular form of suppuration, extended pathological research proves more and more that an absolute line of demarcation cannot be drawn between the indubitable result of inflammation, and the various forms of what is now called tubercle.

We have just adverted to the resemblance between the texture of miliary granulations and certain forms of chronic inflammation; and those familiar with pathological anatomy will acknowledge that there is no constant line of distinction between purulent and tubercular matter; and that, although they are generally different, yet cases frequently present themselves in which they so completely pass into each other that no physical characters appropriate them to either kind of lesion. That tubercle may sometimes be developed without any inflammatory process, is sufficiently proved by the examples in which it occurs in various parts of the body at once, apparently as a modification of the ordinary nutritive secretion of the part under the influence of a peculiar diathesis; but the prevalence of this diathesis in a lower degree, although insufficient in itself to produce tubercle, may give a tuberculous character to the products of any inflammation that may arise, and this the more effectually as the inflammation is asthenic and defective in the energy of its orgasm. Although we thus express our conviction of the connection of this subject with that of pulmonary consumption, we must not entrench on the article devoted to that disease, and we will close these remarks by quoting from the little work before noticed the conclusions to which we were then led, as they develop what we consider still to be the full extent of the relations of inflammatory to tubercular disease. "The lungs may become infested with tubercular matter:—1. by the tubercular suppuration of the indurations, whether granular or diffused, which we have been induced to consider chronic inflammations of the pulmonary tissue, this being the natural termination of such inflammation: 2. by tubercular suppuration of other inflammations of the tissue; this effect being determined by the prevalence of the tuberculous diathesis:* 3. by secretion in tissue bearing no marks of other lesion, the tubercular matter being here deposited through excess of the tuberculous diathesis," modifying the common nutritive secretion of the part. (Rational Exposition, &c. p. 160.)

The symptoms of chronic pneumonia supervening on an acute attack partake of the general character of this modification of inflammation. Thus, although the general fever abates, and the functions are in some degree restored, yet the pulse is still quick, the breathing short, the cough remains, the expectoration often assumes the characters of that of chronic bronchitis, and the patient, although he recovers in some degree his appetite and strength, looks ill, and does not advance beyond a certain degree of amendment. Percussion and auscultation will discover the remaining disease by the dull resonance of the corresponding part of the chest, and the absence or bronchial character of the respiratory sound. The solid state of the lung which causes these signs, if it be not removed by the sanative processes of nature aided by remedies, will gradually induce other disorders: either it may terminate in suppuration, and, if extensive, it will endanger life by the unmanageable decay in which it involves the lung, and which, if not identical with tubercular disease, bears to it a strong resemblance in its symptoms and course; or remaining a solid obstruction to the circulation and respiration, it occasions dropsy and that cachectic state which we find induced by chronic pleurisy, pulmonary emphysema and other local diseases which permanently infringe on these vital functions; and here again a condition is produced which is on all sides admitted to be most favourable for the development of genuine tubercular consumption. In fact, however we study the relations of inflammation and tubercle, whether rationally or from evidence, whether at the bedside or in the dissecting-room, we are continually meeting with proofs of proximity between them, which are far too constant and regular to be ascribed to accident. Were we to describe the symptoms of pneumonia originally chronic, we should only have to state phenomena which are detailed in another article. See Tubercular Phthisis.

Treatment of Chronic Peripneumony.—If this disease is so exceedingly rare as it is supposed by Laennec to be, we might pass over the subject of the treatment entirely, as he does; and if, as we believe, it constitutes a form of consumptive disease, we must refer to the article on Tubercular Phthisis for its fuller consideration. We would, however, make one remark to reconcile views which may otherwise appear conflicting; that because tuberculous disease may be developed and hastened by a form of inflammation, it does not follow that consumption is to be treated by depletions and abstinence. We have often seen that these measures do not restrain the asthenic and chronic forms of inflammation, while they may injure the general power of the constitution, and that the combination of treatment most useful in these cases is a mild tonic and nutritive regimen, with external counter-irritation and whatever alterative the case may suggest. We believe these to be the most successful measures in the disease in question, which may in addition require expectorant and other remedies for particular symptoms, and the removal of the occasional causes by resorting to another climate. We have

* See *Dr. Alison*, on the Origin of Tuberculous Disease, Trans. of the Medico-Chir. Soc. Edin. vols. i. and ii.

known a case of chronic solidification of the lung, which had already begun to exhibit the commencement of a phthisical career, cured under a course of iodine internally, with external counter-irritation, and careful protection from transitions of temperature. The prospect of a cure will be in proportion as the disease is limited in extent, and the constitution strong and free from that diathesis which we have noticed as the cause of the worst form of consumptive disease.

C. J. B. Williams.

PNEUMOTHORAX. — This term (compounded of *πνευμα, ατος—θωρηξ,*) signifies a collection of aëriform fluid in the cavity of the pleura. As such a pathological state had not attracted notice till modern times, it remained undistinguished by any proper appellation till the beginning of the present century, when the word pneumothorax, invented by M. Itard, was adopted to designate it. It has been objected at various times to this term that its etymological composition is incorrectly formed, but closer examination into the analogies of Greek derivatives proves this to be unfounded; and, moreover, it appears now to be so well established on the basis of authority and general adoption, that any change would be both improper and impracticable.*

Gaseous collections have been frequently noted as occurring in some of the serous cavities as well as the other tissues of the body. It had been often observed that air escaped on opening the thorax in necroscopic examinations, and the attention of surgeons was occasionally arrested, during the operation for empyema, by a rush of air through the canula preceding the flow of matter. The effusion of air consequent on laceration of the lung by fractured ribs was known, but was classed with emphysema, and called *emphysema thoracis*. Those casual observations had not been reduced to any digested form, nor did they lead to investigation of the true origin of the elastic fluid, as it was universally assumed that the latter was extricated by decomposition from the purulent matter. It was not, therefore, till 1803, when M. Itard published his dissertation, that air in the pleura came to be considered as not a mere accidental complication in some rare cases of empyema, or as only occurring after death, but to constitute in itself an important pathological condition. Although thus much appears to have been established by the researches of this author, the insufficient advances which morbid anatomy had made, and the incorrect notions which prevailed as to the pathology of thoracic diseases, prevented him from going much further. His views corresponded with the old crude idea of the chemical decomposition of pus. He regarded it as always consequent to and depending on a latent phthisis, and ascribed the production of the air to the decay of the lung by means of a chronic suppuration, and the long retention of the pus in a shut cavity, which caused a partial absorption of the stagnant liquid, and its decomposition into an aëriform fluid: this was the state of knowledge on the subject till the time of Laennec, for whose labours it was reserved to investigate its true nature, and to give it its proper place in nosology. His researches have attached to pneumothorax the highest degree of importance, and we do not think that the genius and industry of this great physician have been more signally displayed in any of their achievements for thoracic diseases, than in the comprehensive illustration which he has given of the pathology and diagnosis of this affection.

Two sources are recounted by which air in the cavity of the pleura may originate. It has been said to be generated within that membrane, and it may be introduced from without. The former, we have seen, is the origin to which M. Itard ascribes it in every case, and Laennec assents to this manner of explaining the six cases which he cites. In all these instances the pneumothorax was accompanied by a pleuritic effusion, the consequence, as they relate, of phthisis; and the latter author is of opinion that the gaseous development was caused by a decomposition of part of the albuminous matter suspended in the puriform effusion. This, he adds, is rendered probable by the odour of sulphuretted hydrogen which the air exhaled. Neither this nor any of the other circumstances by which they were attended would incline observers at the present day, furnished with precise and more extended information on the subject, to agree to this method of explaining it. On the contrary, the examination of their details exhibits sufficient evidence to authorize us in referring them to a cause (the admission of air from without) which will be hereafter mentioned, as by far the most frequent of all. It has never been satisfactorily proved, and it seems to us an extremely problematical circumstance, that pneumothorax ever occurs by the putrefactive decomposition of a pleuritic effusion. The other processes by which air may be developed within the pleura, as recounted by Laennec, will be afterwards adverted to. It may be here stated that some of them are only conjectural; for the experience of one individual could not supply well-ascertained facts sufficient to establish by observation all its causes and their relative frequency, particularly as he had to bring to maturity his own discovery of the method of exploring them.

* We find that Dr. Elliotson, in his lectures, has reproduced the objection of Piorry to the term pneumothorax (Lancet, 1 Dec. 1832, p. 305.) He states that these compounds are always made from the dative singular, and that the word should be *pneumatothorax*. With unfeigned deference we would submit that the majority of these compounds are not formed from the prolonged dative, as *αἱματι, ὑδατι*, but from the nominative *αἱμα, ὑδωρ*, by changing its termination into *ο*,—for example, hemorrhage, hydrothorax, &c. Pneumothorax, formed according to this analogy, is a more perfect hellenism, and (as will be easily conceded) much more euphonious than the other formation. Its true signification also is "air in the thorax," and not "lung in the thorax;" for it will be observed that if this were necessarily its meaning, it would follow, by the same analogy, that hydrothorax signifies, not "water in the chest," but "hydra in the chest," and to represent the former it should be *hydatothorax*. Professor Elliotson has permitted himself to overlook his own principles in saying that pneumothorax means "lung in the thorax," for even if, as he insists, the formation from the dative were followed (as we acknowledge it has been in a *few* instances), it is immediately apparent that "lung in the thorax" would be *pneumonothorax, μνευμων*, pulmo, *ονος, ονι*. In arranging the terminations of these compounds the ancient Greeks paid especial regard to the euphony, but this does not seem to have been the case with their successors who lived at the decline of the language, for to these are certainly to be referred the few compounds in *ato*, as hæmatocele, pneumatocele. The last word was even changed from the original pneumocele: vide Laennec, de l'Auscultation, tom. ii. p. 241, note. Edition 1826.

It may be laid down as proved by the recorded experience of medical men, that where pneumothorax exists the air has been introduced from without; for cases of an opposite description are so rare that they must be considered as exceptions to the rule. This position will not be called in question, we apprehend, by any one who has devoted some attention to this subject. Air, then, may enter the serous membrane and form a lodgment in the sac of the pleura, either from the lung and bronchial tubes, or by the thoracic parietes through the skin and intercostal spaces. An example of the former is afforded by the rupture of the pleura from the bursting of a tubercular cavity communicating with the bronchial tubes, and of the latter by the opening of an anthrax of the intercostal spaces through the costal pleura, or by the pneumothorax consequent on penetrating wounds of the chest, whether accidental or artificial. We proceed now to expose the phenomena of this affection; but as most of these are common to it from whatever source it arises, it will be found advantageous to consider them in a description of it as resulting from one particular cause; namely, the first which we shall mention.

Pneumothorax produced by the bursting of a tubercular abscess into the pleura.—This species of the affection is, beyond all comparison, more frequent than all others. If we were to conclude from the experience of the medical men in Dublin who have given most attention to the subject, it might be asserted that it constitutes fully nine-tenths of the cases of pneumothorax, with the exception of the traumatic variety; and this, or even a greater proportion, is established by the cases found in medical writings since the publication of Laennec's work. This great comparative frequency, together with the importance which it derives from its connection with the history of phthisis, have concentrated upon this form nearly the whole interest which the malady possesses.

Pathology.—The cavities which the progressive stages of aggregation and softening of tubercles form in phthisis are situated almost invariably in the superior lobe of the lung, and it is at the very summit of this that in general the excavation is largest. While the pulmonary parenchyma disappears before the expanding walls of the abscess, a remarkable circumstance is observed in examining the manner in which this tissue is destroyed, which shows that nature was making at least some struggle against her too powerful enemy. It is found that the bloodvessels are not engaged in the ulceration, but become obliterated, and traverse the empty cavity as solid chords. The bronchial tubes, on the contrary, are involved in the destruction, and their divided ends preserved open, levelled to the surface of the parietes of the sac, and forming a part of them. This double provision has obviously for its ultimate end to prevent sudden hemorrhage, and to allow of the evacuation of the tubercular matter. (See Phthisis.) While the latter is accomplished, it is manifest that the same passage which permits the matter to escape admits the inspired air to fill the space which it occupied. If life be prolonged, the parietes are always enlarging their limits, and thus, although slowly, marching towards the surface of the lung. Those centrally situated do not often arrive at the surface, but others, originally developed more superficially, extend in their progress to the serous membrane, which at length becomes in contact with the membrane forming the wall of the cavity. Here the spreading further is generally restrained by the throwing out of lymph and the formation of adhesions, but not uniformly, for in many instances the pleura is perforated. The immediate consequence of this is that the contents of the tubercular abscess, including softened tubercle, muco-purulent matter, and air, are precipitated into the cavity of the pleura. The reception of these contents into the pleura could not take place if the lung were to remain as in its natural state, in perfect apposition with the costal parietes, but a new condition is induced on the occurrence of perforation which permits it. In the physiological condition the lung is retained in a state of distention beyond its mean capacity by the expansion of the thorax, a condition which its highly elastic structure allows. It is, even at the extremest expiration, we believe, still kept more expanded than its elasticity would allow if left to itself, and not counteracted by the atmospheric pressure. The latter force, however, certainly stretches it during inspiration, when the capacity of the thorax is much enlarged; but when perforation of the pulmonary pleura takes place, the pressure becomes equalized on the external and internal surfaces of the lung, and now the elasticity is permitted to act, which it immediately does by producing the recession of the lung from the costal pleura. By this means a space is left and instantly filled with air from the bronchial tubes, which have now, by the intervention of the phthisical cavity, a free communication with the sac of the perforated pleura. Such is the mechanism by which the atmospheric air gets ingress in this variety of pneumothorax.*

To physicians who have opened many subjects that have died of phthisis, it would at first only seem a surprising circumstance that pneumothorax is not a more frequent occurrence. They are accustomed to find very frequently at the summit of the lung phthisical cavities, bounded merely by the pleura itself, or with so thin a plate of lung interposed that it is scarcely any protection to it. Yet it is well ascertained that perforation rarely or ever takes place at the summit, where we so frequently meet with so slender a barrier to prevent it. The explanation of this is found in the fact that the summit of the lung in which large cavities exist is always covered by a dense cap of false membrane, which effects its firm adhesion with the opposed costal pleura. It would seem that, as

* It will be observed that we have adopted Dr. Carson's views with respect to the agency of the elasticity of the lung in respiration. We think that, so far as we have stated them, they are consistent with our experimental knowledge on the subject, but we are not ignorant that many think them contradicted by the phenomena of wounds of the chest, where *hernia* of the lung succeeds. It is almost certain that the latter is caused by a vital irritability, and not by mere elasticity, as we see that the invariable action of the latter in the dead subject is to contract the lung when the internal pressure is removed. The forces which act on the lung are by no means sufficiently investigated; the experiments which have been made on the eighth pair seem quite inconclusive on this subject, and until it be further elucidated, many phenomena connected with asthma, hysteria, protrusion of the lung, and its re-expansion after collapse, must remain unexplained.

the parietes of the cavity approach the surface at the summit of the lung, an effort of nature is made to intercept the escape of the contents of the tubercular cavity, by the formation of these adhesions. A chronic inflammatory action in the pulmonary tissue always surrounds the cavity for a lesser or greater extent, and, as it were, precedes its progress towards the surface. The effect of this is visible in the plates of lung often found to intervene between the cavity and the surface, which are generally in a state of dark-grey hepatization. It is by this same inflammation that the false membranes are thrown out which effect the adhesion of the pleural surfaces,—those, we mean, which are met with covering the summit of the lung in phthisical patients. It is found that in the same proportion as the cavity advances to the summit, the cap of false membrane becomes more strongly organized and thicker, and forms thus an effectual protection against perforation as far as those adhesions extend.

It is important to remark, with respect to those dense membranous cases, that as it is in the summit of the lung that cavities usually exist, so this part is much more favourably circumstanced for adhesion than any lower part; for the sliding motion of the lung on the costal pleura is greatest at the diaphragm, and diminishes in proportion as we ascend to the summit, where it is little if at all moved by the respiratory action. A constantly quiescent apposition of the two surfaces is that which most advantageously promotes the formation of adhesions, and, as we have just stated, this is possessed only by the summit, and decreases as we descend from this. These considerations explain the observation, well known to all conversant with phthisical dissections, of the existence of the membranous coverings at the summit of the lung. They moreover show the reason, that while it is in this place tubercular cavities generally first attain the surface, perforation of the pleura most seldom occurs here, and they also lead us to anticipate the fact that the perforation *does* generally take place just below the line to which the adhesions extend.

The rupture may occur in any of the lobes of the lung, but the inferior part of the upper lobe, and the superior part of that beneath it, is the place where it has been most usually observed. In a great majority of cases it has been found to happen on a line with the third rib, posteriorly about the costal angle, and, as we have said, just under the reflection of the false membrane by which the superior lobe is so generally adherent. But although this is its usual situation, it is obvious that it may happen at any part of the pulmonary surface. It has even been known to happen at the base of the lung lying on the diaphragm; but this must be a very rare situation, both because adhesions are common here from the apposition being little disturbed, and because tubercular cavities are uncommon at the base of the lung.

The existence of a large cavity, or even of numerous tubercles, is by no means necessary to the production of pneumothorax. We have known it to occur where the cavity which caused the perforation was smaller than a nut. Andral and others have met with cases where only five or six tubercles existed in the lung in which it happened, and Dr. Townsend had one remarkable case where it followed on the bursting of one single tubercle, which was unfortunately developed immediately under the pleura, while the whole of the lung beside, as well as the other lung, was perfectly free from them.

The inevitable consequence of the escape of the contents of the cavity and of the air into the pleura is the immediate accession of an acute pleuritis of a more or less intense character. This supervenes when scarcely any thing but atmospheric air is received into it, for this proves as decidedly irritant to the membrane as any other of the foreign substances which enter together with it, a fact which appears demonstrated by viewing the false membrane which follows the pleuritic effusion. The latter is found to be as thick and well organized at the superior and middle parts of the pleural sac, (where it could only receive the irritant impression from the air,) as the base of the sac upon which the fluid contents of the cavity are emptied. The lung being separated from the costal pleura at the first moments of the perforation, (as we have described,) becomes now compressed both by the air and the pleuritic effusion, so that, unless it be retained in points by old adhesions, the compression against the spine and mediastinum leaves a large proportion of the pleural cavity filled with air and fluid, constituting the double lesion of empyema and pneumothorax.* (See Empyema.) If the consequences of the perforation be not speedily mortal, the lymph effused by the pleuritis soon becomes organized, and forms a factitious membrane overlaying the whole surface of the compressed lung and costal pleura, where the air has been able to penetrate. This false membrane is not to be described, as some have done, as a thickening of the pleura. Even in its most perfect state of organization it may be perceived to be a deposition *upon* the pleura, which membrane lies under it, (although incorporated with it,) of its natural thickness. The lung itself lies compressed and flattened against the spinal column and mediastinum. In cases which have lasted some time, its diminution of volume proceeds generally till it is reduced to about one-fourth, and then, if its substance be cut into, the bronchial tubes and vessels are so matted up in its condensed tissue as to present the appearance called carnified lung. (See Empyema.)

While the false membrane forms a general lining for the sac of the pleura, the orifice of the perforation is spared, and the communication between the bronchial tubes and this cavity preserved. The perforation becomes converted into a fistulous opening with a smooth round edge. This orifice has a tendency to increase in diameter, and often attains the size of the tubercular cavity which originated it, but it rarely passes the size of a shilling. We lately had an opportunity of examining three fistulæ which afforded exquisite examples of the state of those perforations when they attain to a chronic condition. Their surface extended nearly across the cavity whose bursting formed them, and was covered with a

* This constant complication of pleuritic effusion with pneumothorax has given occasion to some to denominate it pleuro-pneumothorax.

smooth membrane of a serous aspect similar to that forming the general empyematous sac. They had the appearance of a shallow *cul-de-sac* about a line in depth, and the largest of them had the diameter of a shilling. On examining a little closely, a probe passed under the circumferential rim of the apparent cul-de-sac into a bronchial tube which communicated with a larger cavity. The disposition of the fistulæ here described is very common, viz. the perforation formed by the remains of a very small tubercular cavity, and the latter connected with other larger cavities by means of bronchial tubes.

The closer anatomy of these fistulæ presents circumstances which are particularly worthy of attention. The bronchial tube by which communication is maintained between the orifice and larger cavity is almost invariably found to open upon the face of the fistula towards the sac in an oblique manner from above downwards. This disposition is noticed as occurring in some of the cases detailed by Dr. Duncan in the 28th number of the Edinburgh Medical and Surgical Journal, and we have witnessed it very strikingly displayed in cases which lasted for a certain period after the perforation. The effect of this is to convert the orifice of the opening into a valvular structure, and as it were to aid in the accomplishment of this object, the superior rim of the opening is sometimes observed to be prolonged downwards for a short space over it. The method by which this structure is produced it is difficult to explain, but the end which it is intended to accomplish appears more obvious: at least an attentive examination of it in a strongly marked instance satisfied our minds that it results from an attempt at obliteration of the fistula by a process of nature. On the smooth face of the opening in the case alluded to, there were five small depressions which appeared to be stopped-up bronchial tubes, and the fistula which remained at the upper part was far advanced in the valvular structure. It seemed to us that those tubes were obliterated whose smallness and direction afforded the greatest obstacle to the entrance of air, while that which remained pervious was of the largest size; but what we would particularly advert to as explaining its resisting the process of obliteration, is the nearly vertical direction which it had with regard to the lung. According to our view, this position favours remarkably the entrance of air in such a case, as it lies directly in the line of the action of the diaphragm, by the contraction of which, almost solely, the air is drawn into the cavity in pneumothorax. Another circumstance bearing on this subject which was noticed in the same dissection* should not be omitted. ' The lining of the bronchial tube which formed the fistulous communication, a track of about two inches, was quite changed from the character of mucous membrane; it was no longer pulpy and soft like the latter, but partook more of the serous character, and there were remarked all along it firm granulations of considerable size. The same change was observable in the large excavation from which the fistula led; its lining was more like the lining membrane of the heart than the usual soft membrane which forms the secreting surface of phthisical cavities. (See Phthisis.) These observations go some length in explaining the mechanism of these oblique fistulæ, and we think they furnish also an intelligible and just account of the object which they are intended by nature to subserve, which we are led to conclude is an attempt to obliterate the fistulous orifice.

The general membrane of the sac is a highly organized secreting surface, and appears to be peculiarly susceptible of inflammation and its consequences. It must, indeed, be supposed to be in a continual state of chronic irritation, from the presence of the atmospheric air to which it is constantly exposed. There are frequently found upon it more or less organized albuminous concretions, the result of acute attacks of inflammation. These exudations are either general over the whole sac, or partial. They sometimes surround the aperture in the lung so as to narrow it, and cases have been observed where it has been closed altogether by them. The latter event would be most likely to occur† where the fistula is small and recent, or, on the other hand, where the valvular structure is far advanced. Another result of inflammatory action which it is not uncommon to find on the sac, is the existence of small erosions with a dark and irregular base and circumference, which resemble small gangrenous eschars more than they do common ulceration. These exhale generally a fetid odour which gives them also the character of spots of gangrene; and it is a fact which is confirmed by experience, that the sac is much more liable to gangrenous inflammation in empyema with pneumothorax than in simple empyema. The erosions just described sometimes penetrate the sac and pleura, and at other times they are not so deep, but go no further than the thickness of the false membrane. Their existence cannot but suggest the idea that perforation may occur by the ulcerative process originating in the pleura, and being propagated to the lung and bronchial tubes, as well as the contrary way, which we are considering in this section. The occurrence of pneumothorax originally in this way is, however, extremely rare; but we believe that, when it has already for some time existed, additional fistulæ are occasionally formed in this way.

The contents of the sac are in every case air and purulent matter. In the early stages of the affection the latter fluid is the secretion of the pleura itself, the effect of the acute pleuritis which follows the eruption of the air. When it has advanced to a more chronic duration, the adventitious membrane thrown out by the pleuritis becomes itself the secreting surface whence the fluid is derived. Its characters vary considerably, (see Empyema, Pleuritis,) and are influenced by the duration of the disease, vigour of the patient, and other circumstances. For the most part it is found to be a greyish turbid serum, through which homogeneous pus is mixed, and having an

* For an account of this dissection we refer to the May number of the Dublin Journal of Medical and Chemical Science.

† We are persuaded that this has been the state of things in many of the cases of pneumothorax on record, where it has been reported that examination failed to discover any fistulous communication.

abundant stratum of soft albuminous coagula at the bottom.

We have already marked the error which prevailed long after the discovery of pneumothorax, in supposing that the air was formed by the putrefactive decomposition of the pus. Such a decomposition of this fluid does not take place, but, on the contrary, it is generally remarked that it is inodorous, and free from any evidence of such a process. It is true that in some cases both air and fluid exhale a fetid odour, but in these we must search for other causes than the putrefaction of the fluid; for if this happened in one instance, it should happen in all, as the laws of chemistry do not alter or suspend their action, which would be implied by this hypothesis. In the instances in which we have noted the contents of the sac to be fetid, there was always a gangrenous state of the pleura to which the fetor was evidently to be ascribed; and as we have shewn that gangrenous ulcerations of the sac are not uncommon in pneumothorax, we are inclined to believe that they will be always found where the putrid odour is exhaled by the purulent matter.* The absence of the chemical decomposition of the pus is a fact which is now fully proved by experience; but when we consider the conditions to which it is subjected, it appears to be nothing wonderful that the idea was so long entertained, but rather remarkable that it does not invariably happen. It is constantly exposed to a warm temperature and to atmospheric air, which, together with moisture, are the essential promoters of the decomposition of organic compounds. Yet we have witnessed a case where these conditions existed for a year and a half, in which the pus was quite free from odour, and in all its qualities unchanged by the atmospheric contact. We are unable at present to go any length in discussing the cause of this curious circumstance, but we would observe that rest is a condition favouring chemical decomposition, which is absent in the present case. Some have considered that it is sufficiently explained by the fresh supply of animalised fluid, which the surface of the sac is supposed to maintain, by a continual secretion and absorption. The blood, when effused into the pleura, has been sometimes observed to remain fluid. We are not ignorant, as we have said, of the explanation of these facts, but they seem to prove that animal fluids have some power of resisting the laws of chemistry while preserved in contact with the living solid.

The air enters the sac through the fistulous opening during inspiration. When allowed to escape by a puncture of the thorax, it generally proves to be an inodorous gas, or possessed of a slight sharpness, but, generally speaking, it differs little from the atmospheric air whence it was originally derived. The same gaseous elements have been found to make up its chemical constitution, which has been examined by Dr. John Davy, (Philosophical Transactions, 1824,) and Dr. Apjohn, (Transactions of Association of College of Physicians, Dublin, 5th vol.) The following was its composition in Dr. Apjohn's analysis, which is the more recent of the two.

Carbonic acid	8
Oxygen	10
Nitrogen	82
	100

This coincides nearly with the composition of expired air as deduced from the investigations of Allen and Pepys, and it is by no means improbable that the surface of the sac acts on it in a similar manner with the air-vesicles of the lungs. Such an action has been, indeed, proved to have existed in Dr. Davy's case, in which analyses of the air were made at different periods. By a comparison of the latter, an interesting fact was deducible. It was found that the quantity of carbonic acid increased as the strength of the patient decreased, and the air which was collected twelve hours after death contained a double proportion of this gas.

In the great majority of instances the air, although free to enter the cavity, is either partially or totally prevented egress during expiration, owing to the valvular disposition of the fistulæ which we have adverted to above. When expiration takes place, the air of the cavity, compressed by the contracting thorax, forces the sides of the fistula together, and thus closes it, exactly in the same manner as the valve of the bellows prevents the air from going out by the aperture through which it entered. The consequence of this is, that the air exerts a pressure within the sac which is always increasing as long as the communication remains open. This compression is fully sufficient to account for the reduced size and flattened appearance of the lung which has been described above, and for the dilatation of the intercostal spaces, which is equally a phenomenon of pneumothorax. It has been a debated point, what part the air, and how much the fluid, contributed to the production of this internal pressure. To us it seems evident that the compression must be nearly altogether attributed to the air, and that the purulent matter exerts pressure only as it is itself acted on by the elastic fluid. The force with which the latter escapes when a small puncture is made in the parietes of the thorax, even some hours after death, (when a diminution of the pressure certainly takes place,) is well known. A fact which occurred in Dublin illustrated in a decisive manner the pressure which the fluid receives from the air. Paracentesis was performed on a man who laboured under pneumothorax with empyema, and the puncture of the chest was made below the level of the fluid, the evacuation of which was considered the chief object. Immediately on the entrance of the canula, the matter was projected through it with surprising force and to a great distance. Its forcible exit continued until it was nearly all evacuated, diminishing, however, towards the end of its flowing. This projection of the matter was undoubtedly to be ascribed to the great compression under which the elastic fluid existed. With respect to the relative proportions of the air and fluid there is the greatest variety. In the majority of cases the space filled by the air is much greater than that

* The fetidity which the bronchial mucus is often known to possess in phthisical patients may be another cause imparting bad odour to the contents of the sac in pneumothorax, as it has generally free access to it through the fistula.

which the fluid occupies. The nearest ratio might be set down as two-thirds air and one fluid. These proportions, however, vary not only in different cases, but also in the same at different periods. We are enabled often to ascertain that the fluid gains on the air, and sometimes, though seldomer, that the air increases at the expense of the fluid. In an interesting case detailed by Mr. Smeal, (Med. Chir. Review, July, 1831,) the fistula became obliterated from the formation of a coagulum, and speedily afterwards it was observed that the air became absorbed, and the fluid pari passu increased. This fact proves the manner in which the proportion of the elastic fluid is preserved, and moreover shows the power which the adventitious membrane possesses of absorbing air, as Nysten's experiments had already done for the pleura.

History and Diagnosis.—As the species of pneumothorax which we now describe is the consequence of phthisis, the history of an individual case, if it be investigated with due precaution and diligence, will almost universally demonstrate that cough, hemoptysis, emaciation, night-sweats, &c. (see Tubercular Phthisis,) have existed before the signs peculiar to pneumothorax betray its presence. It happens generally that phthisis has gone on to a very advanced stage ere this distressing complication is brought under the observation of the physician. This is, however, not entirely owing to its invariably occurring at a late period. Somewhat of it is attributable to the circumstance, that the means of its diagnosis have been hitherto scantily disseminated amongst the mass of practitioners, and to their not being used with sufficient confidence by those whose education has embraced them. Auscultation and percussion are now, indeed, daily becoming more practised and relied on, and as this advances it is accordingly found that many more cases are discovered, and moreover it is occasionally detected in the comparatively earlier stages of phthisis. From what has been related in the foregoing section as to its being known to result from very minute cavities, or even from a single tubercle, it follows that it is an accident which may occur in the earliest periods of the history of phthisis, even when the phenomena of the latter are so transiently marked as to be doubtful, and to allow of fallacious hopes of recovery. This, which we should anticipate from acquaintance with its pathology, has been observed in actual practice; its supervention has been witnessed at the very commencement of phthisis as well as at its close, so that what experience teaches is, that while the later stages are more exposed to its occurrence, it may happen at the period at which only the faintest suspicion of phthisis has as yet existed.

The means for the diagnosis of pneumothorax are the rational symptoms and the physical signs. We shall consider these separately, comprehending under the latter the signs derived from succussion, percussion, and auscultation. In the first place it is to be remarked that at the first occurrence of the pneumothorax, a striking change takes place in the entire class of symptoms and physical signs. Before this event there have been present, in a more or less perfect state, the phenomena of phthisis, but afterwards those which we proceed to describe as the characteristics of pneumothorax. This change, then, we would call attention to as in itself an important commencement of the chain of symptoms. The moment of this change is generally perceptible to the patient himself, and when this is the case, he dwells much upon it in his description to his physician. He sometimes feels, in fact, the air passing into the pleura at the moment of the rupture, as also the rupture itself. This sign did not escape the observation of our older physicians, although they were unacquainted with the pathological conditions which gave rise to it. Morgagni recites a case in which this sensation was accurately described, as observed by Willis and Lower: "Casum habes in sepulcreto descriptum adolescentis qui se Willisio ac Lowero curandum tradidit. Is post immodicas equitationes, aliasque corporis diuturnas exercitationes cum aliquandiu in sinistrâ thoracis parte eum sensum habuisset, qui esse sine internâ compressione non poterat, ibi tandem *sensit disrumpi quasi vas quoddam; indeque per semihoræ spatium in regione istâ ab alto in pectoris fundum cadentis stillicidium non tantum ab eo percipi, sed etiam ab adstantibus audiri potuit.*" (De Sed. et Causis Morborum, Epist. xvi.) This sensation has been, if possible, still more appositely depicted since the pathology of pneumothorax has been cleared up. We find the following description in Louis's forty-first case: "La malade éprouva *tout-à-coup*, du côte gauche de la poitrine, une sensation pareille à celle qui eût été produite par un gaz qui aurait circulé de bas en haut dans toute cette partie du thorax."* This actual perception of the perforation by the patients is an element of the diagnosis which it is so desirable to possess, that the practitioner should never omit to inquire after it, yet it is one which he must learn to dispense with, as many cases occur in which no such sensation has been felt, while in others, in which a certain period has elapsed, it escapes the patient's memory.

Empyema being invariably an accompaniment of this variety of pneumothorax, the symptoms of the latter are necessarily mixed up with those of the former. This circumstance demonstrates the insufficiency of the rational symptoms in detecting it, and partly accounts for the long ignorance which reigned on the subject. We find the symptoms of empyema set down as dyspnœa and pain, cough and expectoration, decubitus on one side, dilatation of the side, displacement of the heart, and depression of the diaphragm, hectic fever. These are found amply discussed as constituting the disease of empyema under its proper head (See Empyema.) The same catalogue precisely makes up the rational symptoms in pneumothorax It now devolves on us to consider them in this regard, and we shall find that accurate observation has been enabled to discover several peculiarities in them as belonging to pneumothorax, which render an account of them quite indispensable to

* Recherches Anatomico-Pathologiques sur la Phthisie, p. 461. The sensation, as related in a case of Dr. Stokes's, strikingly resembled the description of Morgagni; the patient, "while in the act of coughing, had a sensation as of a sudden crack, extending from the shoulder downwards, and felt as if a quantity of liquid was shed out into the left side of the chest." Trans. of Assoc. Dublin College of Physicians, vol. v. p. 337.

its history, and give them some importance as auxiliaries in its diagnosis.

a. Dyspnœa and pain.—These symptoms are to be considered at two periods. First, as they exist immediately on the occurrence of pneumothorax, and secondly, as present during the whole of the remaining duration of the disease. The dyspnœa and pain which follow immediately on perforation are nearly simultaneous with the sensation which we have above described, but they are still more constantly present, and therefore of more value in its diagnosis. The researches of Louis (Op. citat.) have called attention in a particular manner to these circumstances. He regards the sudden supervention of acute pain and overwhelming dyspnœa as a constant attendant on perforation of the lung, and as always indicating the period of its occurrence. They are, indeed, symptoms which are so rationally suggested by a knowledge of the new pathological conditions (viz. the sudden perforation of the lung, its collapse, and the effusion of air &c. into the pleura) which ensue, that they might have been anticipated by *à priori* reasoning, "et à raison de la similitude qui existe entre les circonstances qui accompagnent la perforation de l'intestin grêle, et celle des poumons, on aurait encore pu, ce nous semble, les soupçonner par voie d'anlagie." (Ibid. p. 476.) Louis relates seven cases, in all of which they were present; and we know that in one of them at least they occurred in the presence of the medical men, who were enabled to pronounce on the supervention of pneumothorax from this single circumstance. Their value has been also confirmed by the reiterated observation of them in the experience of others since his publication. We are, then, to regard a sudden access of violent pain in the chest, and of greatly aggravated dyspnœa, as symptoms of the greatest weight, and wherever they supervene in the course of phthisis, the occurrence of pneumothorax should be suggested to the mind of the attendant physician, who should immediately have recourse to other and less fallible means of exploration. Louis observes that the pain, although generally very acute, yet admits of varieties of intensity, and that it is not always in proportion to the sudden breathlessness which the perforation induces; and we find that in one of his cases he notes that the pain was entirely absent.

But here we must not omit to state that instances are not wanting which prove that neither singly nor collectively can these signs be referred to as decisive tests of perforation. Dr. Townsend records a case of pneumothorax from this cause, the commencement of which was marked by neither violent pain nor sudden dyspnœa. (Trans. of Assoc. of Dublin College of Physicians, vol. v.) We have also had a case in which the most careful investigation of its history could not determine the period of perforation from the sudden supervention of these symptoms. (Dublin Journal of Medical and Chemical Science, No. 3.) In estimating them, it is moreover to be remembered that the dyspnœa of phthisical patients is not uncommonly increased by other obscure causes; and, also, we should be on our guard against mistaking for such an occurrence pleuritic pains, which are so common in phthisis, and sometimes are of more than ordinary sharpness, without being by any means connected with perforation.

The dyspnœa which exists during the general duration of pneumothorax is deeper and more distressing than that of simple chronic empyema. This is, doubtless, partly occasioned by the coexisting sources of irritation of the pulmonary circulation which phthisical patients possess. A cause of equal efficacy and more uniform existence is found in the resistance which the elasticity of the air affords to the great pressure under which it exists in pneumothorax. This causes such a condensation of its volume before it produces the compressing effect of a liquid effusion, that even the greatest expansion of the thoracic parietes can but partially overcome its reaction, so that the dyspnœa resulting from their compression is but partially mitigated by the deepest inspiration. Such a condition is not present in simple empyema, as it is obvious, from the non-elastic nature of the fluid, that deep inspiratory efforts may expand the thorax beyond the limits of its compressing action, which therefore does not maintain a constant embarrassment of breathing, as it does not react (like the elastic fluid) on the immediate compression being temporarily withdrawn.

This appears to be the rationale of the aggravated character which the dyspnœa of pneumothorax possesses. The slightest exercise produces great oppression if the patient be able to walk, but ascending stairs causes particular distress. Even the motion of turning or raising himself in the bed leaves him often speechless from breathlessness for a short time. In the latter case we might conjecture that the fluid is in large proportion, as its mere weight has great influence on the breathing in changing the posture.* If the duration of the disease permits it to assume a chronic character, the dyspnœa rather diminishes than increases, although the internal compression shall not be mitigated. This is attributable to that surprising power of adaptation to circumstances which the animal economy enjoys, and which is possessed in an especial degree by the respiratory and circulatory organs. However, whatever fluctuation it may undergo during the course of the affection, as in all thoracic diseases, it becomes aggravated at its close.

The acute pain which ushers in its commencement generally subsides in a short time, and afterwards it runs its course without marked suffering from this cause. But more usually, if the patient lasts, he is subject to violent recurrences of pain which have been traced in some instances to recent inflammations of the sac, and also to the establishment of new fistulæ. These attacks of pain are in themselves additional sources of the dyspnœa; it follows, however, of course, that no secondary occurrence of inflammation, nor opening of new fistulæ, can produce the same degree

* This remark as to dyspnœa produced by sudden change of posture, is a valuable diagnostic of fluid effusions of any kind in the chest, particularly where these complicate pneumothorax. The description which Morgagni gives of it in what was anciently called convulsive asthma, must be appropriated to such cases, and particularly to that which we treat of. "*Statim anheli fiebant, ac velut moribundi respirabant*, cum retrorsum caput moverent, aut supini," &c. De Sed. et Causis Morb. Epist. xv.

of pain or overwhelming dyspnœa which ensues upon the original perforation.

b. Cough and expectoration.—These symptoms, which are more or less present in every pulmonary disease, form no essential accompaniment of pneumothorax. No case indeed is altogether free from them, but they are rather to be classed with the signs of phthisis which has preceded it, or with those of the pleuritis which accompanies it, than to be referred to the affection itself. On more than one occasion we have been enabled to mark their connection with bronchitis supervening in the opposite lung. Even a slight degree of cough is harassing to the patient, and in the rare cases where it remains frequent it causes extreme anguish. It is performed in a very laborious manner, in which an instinctive endeavour to refrain from agitating the contents of the thorax is perceptible to the medical observer. This gives to it a peculiar expression, so that we find sometimes set down, in accurately taken cases, "dry, husky, ringing," as the character of the pneumothorax cough. It has occurred to us, while observing it, that it resembled very closely the cough of a broken-winded horse. The distress which it occasions makes it important to attend to this symptom, and an acquaintance with its peculiar character may assist in distinguishing the affection. It is, however, sometimes nearly entirely absent. In a case of Dr. Stokes's, the dissection of which we attended, a complete cessation of both the cough and expectoration took place simultaneously with the occurrence of pneumothorax, but they returned with severity when tubercles in the other lung began to soften.

The expectoration is for the most part scanty, and possesses no peculiar characteristic, but in some rare cases it happens that the fluid contents of the pleural cavity make way through the bronchial communication. When this occurs, the evacuation of the matter is attended with terrible dyspnœa, threatening, when it is copious, sudden suffocation.

It is known that the patients who are operated on for empyema sometimes acquire a power of assisting the expulsion of the matter which collects posterior to the operation, through the wound of the side, by forcible expiratory efforts and coughing. We mention this to notice the case of a porter at the Meath Hospital, affected with pneumothorax and empyema consequent on perforation of a tubercular abscess. This man possessed an analogous power of *expelling at will* the fluid of the cavity through the fistula in the lung. He was accustomed to exert this whenever it accumulated to a certain quantity, by leaning over the bedside so as to invert the thorax, and thus decant it through the mouth, aiding its escape by some efforts of coughing. Another singular circumstance worth noticing was remarked in Dr. Stokes's case just referred to. When the irritation of the opposite lung caused a return of the expectoration, the patient was sometimes unable to raise it out of the trachea, but was sensible of losing command over it when it ascended as far as the top of the sternum. In fact he felt convinced that it used to drop down the bronchus leading by the fistula to the pneumothorax cavity.

c. Decubitus.—If the fluid contents of the pleural cavity be very small in quantity, the patient may recline indifferently upon either side or upon the back; but in the majority of accurately observed cases he has been found to lie in preference on the affected side. This is the conclusion that our inquiries have led us to; but different statements are found in authors on this subject. It is stated by Schmalz, (Versuch einer Medizinisch-Chirurgischen Diagnostik, Dresden und Leipsig, 1825, p. 99,) and other writers, that the decubitus is invariably on the sound side in pneumothorax, and that this affords a striking mark of distinction between it and empyema. We cannot help suspecting that this opinion has been originally rather conceived from theory than deduced from observation, and we the more readily make this remark from observing the occasion and the manner in which Dr. Duncan (Edin. Med. and Surg. Journal, No. 28, p. 327) announces it. "The change of decubitus," says he, describing a case, "*is exactly the reverse of what it ought to have been*, for in empyema the patients commonly lie on the affected, and in pneumothorax, on the sound side." The reasoning, too, with which this has been advanced (See Med. Chir. Review, July 1830, p. 455) is only applicable to the infinitely rare case of simple pneumothorax, and not to that which results from perforation, for this is always accompanied by empyema. It is true that in empyema the dyspnœa is caused by the pressure of fluid alone, and it is chiefly for the purpose of relieving the mediastinum and opposite lung of its weight and pressure that decubitus takes place on the affected side. (See Empyema.) But in pneumothorax the compression of the internal organs is as complete, if not more so, although caused by air, and if the *weight* of even an inconsiderable quantity of fluid should be added to them already suffering under this great compression, it will be an object with the patient instinctively to obviate this by lying on the affected side. As far as our experience goes, this position has been, *cæteris paribus*, always preferred. However, it not unfrequently happens that the violence of the pleuritic pain forces the patients to turn to the sound side in spite of the increased oppression which the change induces. We have witnessed a case in which the struggle between the pain augmented by lying on the affected side, and dyspnœa aggravated by changing to the opposite, was extremely distressing; but here the want of breathing triumphed over the pain, and compelled the poor patient to endure the latter as the lesser evil. When the intensity of the pain has passed, if a change has taken place during its continuance, decubitus on the affected side is usually resumed.

d. Dilatation of the side.—On a comparison of the two sides of the thorax, it is observed that the side in which the pneumothorax exists is faintly or not at all elevated during inspiration, and on being measured it is generally found to be larger than the opposite. These differences may be observed at a very early period after the perforation, but for the most part they are greatest at the advanced periods of the affection. The average amount of the dilatation is from one to two inches, as in empyema. The enlargement of the intercostal spaces and their occasional protrusion beyond the level of the ribs are also observable in

both, so that, from the mere contemplation of the phenomena of dilatation, there exists no distinctive mark between them. It is said, however, that where they are very conspicuous in pneumothorax, the side is more what the French denominate "bombe" than in empyema. The œdema of the integuments of the side which sometimes attends the latter is not observed, although Louis and others have remarked an œdematous state of the corresponding arm.*

Many instances of pneumothorax are on record in which no difference whatsoever existed in the dimensions of the two sides of the chest. It may be observed that in cases where the air can pass out during expiration from the non-existence or imperfect formation of the valvular arrangement of the fistula before described, the chief source of dilatation, namely, the accumulating pressure of the air, is absent. This valvular structure has not been hitherto much attended to; it has, however, been remarked that in some of the cases where there was no dilatation, the fistulous orifice was very large, rendering it probable that egress from the cavity as well as ingress remain unobstructed. But it must be acknowledged that this suggestion is by no means sufficient to explain the absence of dilatation of the side in many well-authenticated cases, in which the air was proved to have been subjected to very great pressure, evidenced by displacement of the thoracic viscera and other phenomena.†

We had an opportunity of demonstrating that the dilatation of the side varies considerably, and that it may even give place to contraction. At an interval of six months between two measurements of a case, it was found that the pneumothorax side (measuring from the centre of the sternum to the spine of the vertebræ), from being one inch wider had become half an inch narrower than the other. And further, on measuring five months afterwards, it was found to have returned to its former dilated dimensions. We believe that we were enabled to connect this temporary decrease of dilatation with a partial closure of the fistulous communication, and an attempt at cure, as happens when empyema is removed by absorption. The progress of the case, however, (during which other fistulæ formed,) and its termination, did not allow us to confirm this anticipation; but notwithstanding this, the nearly total departure of the tintement coinciding with the contraction and other phenomena left little doubt that such was really the case. (Dublin Journal of Med. Science, Nos. 3 and 8.)

Schmalz says, (Op. citat. Ibid.) "If both sides be engaged, the chest exhibits nearly a cylindrical form." Of the occurrence of double pneumothorax the only two cases recorded that we know of are those in Laennec's work. In the first of these, observed by M. Recamier, the chest is described as "vaste, bombé," terms which have probably suggested the description of Schmalz. Notwithstanding the extreme rarity of both sides being involved, it may not be useless to retain in memory this symptom of general dilatation, as in such a case many of the other signs must be of no avail, inasmuch as they require the contrast which is afforded by the opposite side remaining sound; and it is of the greatest importance to be able to recognise this terrible affection at once, in order to attempt the relief of the dyspnœa by performing paracentesis, the only means which art suggests to prevent speedy suffocation.

e. Displacement of heart and depression of diaphragm.—It appears that less compression is requisite to affect these conditions than to produce dilatation of the side, for the latter has been absent in cases where the heart has been thrust considerably out of its place, and a sensible fulness produced in the corresponding hypochondrium by the depression of the diaphragm. It is here a proper place to remark the singular fact that perforation of the lung and its consequences, in the great majority of cases happens on the left side. Seven of eight cases, which occurred to Louis, were on this side, and we believe that in the cases which have come to our knowledge nearly an equal preponderance existed. So great a disproportion must have been in some degree accidental, for in eight cases described by Laennec the number on each side was equal. However this may be, it is certain that it occurs oftener on the left, and this circumstance makes displacement of the heart a very common and striking feature in pneumothorax. In cases of extreme displacement, the heart's action is both felt and seen beyond the cartilages of the opposite side, but the average extent is not farther than the opposite half of the sternum, or below the ensiform cartilage; for it is found to move downwards as well as laterally when the displacement occurs from left to right. When the pneumothorax exists in the right side, the heart's displacement, for obvious reasons, will be less, but the depression of the diaphragm will be more easily perceived from the protrusion of the liver which follows it. This prominent state of the liver is as truly an effect of depression of the right side of the diaphragm by an aëriform collection as by an empyema; and, as in the latter, it might at first view lead the observer to conclude that the oppression of the respiratory organs was connected with a visible hepatic enlargement. This has been adverted to in the article EMPYEMA; but in a paper on the diagnosis of the latter (See seventh number of Dublin Journal of Medical and Chemical Science) by Dr. Stokes, since published, there are some additional signs furnished, which contribute much to the elucidation of this point of diagnosis. We shall notice here but one of these, which is as applicable in pneumothorax as it is in

* It appears, from Morgagni, that this œdema of the arm has been frequently noted by the older physicians in pneumothorax. "Verum præterquam quod brachium alterum, quod dolebat, œdemate habebat tumidum (qualem tumorem in thoracis hydrope Fantonus pater, et Buchnerus, aliique, et in his Valsalva noster interdum adnotarunt) *cum ad thoracis motum diceret fluctuationem in eo sentire*," &c. Morgagni de Sed. et Causis Morb. Epist. xvi. s. 36.

† See Dr. Duncan's tenth case, Edin. Med. and Sur. Journal, No. 28.; Dr. Stokes's case, Trans. Assoc. Dublin College of Physicians, vol. v.; and five of Louis's cases, marked "Etat exterieur, de remarquable," which amounts to evidence of no dilatation, for this exact observer has noted it particularly in the cases where it was present. In Dr. Duncan's case a method of opening the thorax was practised by Dr. Cullen, which is worth relating. Instead of penetrating the sac at once, which is usually done, he dissected back the ribs and intercostals for a considerable space, so as to expose the external surface of the pleura, which rose up distended and elastic. This way is somewhat more troublesome, but it is very advantageous for estimating and displaying the pressure which the air exerts

empyema. It has, moreover, a peculiar propriety in the former, as it is a palpable sign, and addresses the eye at the first examination; because we apprehend that the effects of pneumothorax and enlargement of the liver could be confounded only where a defective exploration had at first produced an erroneous impression, unless the air be very small in quantity and the fluid copious, in which case the difficulties connected with empyema recur. Dr. Stokes, however, has observed, that where the diaphragm, depressed and rendered convex downwards by the contents of the pleural sac, causes the descent of the liver, there is a sulcus evident to the sight and touch in the right hypochondrium. This is produced by the two convex surfaces of the diaphragm and liver, respectively terminated anteriorly by the edge of the latter and by the inferior margin of the false ribs. It is manifest that such a sulcus cannot be present in the mere enlargement of the liver, let it take place to any extent, as it requires the opposed convexity of the diaphragm for its formation, and this condition is only produced by a liquid or gaseous effusion.

f. Fever.—Whatever has been the condition of the circulation before the escape of the air by perforation, the fever of pleuritis sets in speedily after this event takes place. Its character is necessarily modified by the previous state of the patient's system, but it always conspires to aggravate his sufferings. Much, indeed, of the dreadful distress which ensues is to be ascribed to the increased febrile action which occurs almost simultaneously with the accident. This will be conceived when it is recollected that while one of the lungs is by rapid compression nearly deprived of its function of respiration, the excitement of the heart's action increases the demand for aeration, so that this combination of circumstances often produces a degree of dyspnœa under which the patient rapidly expires. Such an effect of the fever is not more likely to occur in debilitated individuals than in those of robuster stamina; for in the former, although the constitution be more exhausted, this seems fully counterbalanced as regards the effects in question, by the diminished quantity of blood which circulates in the system of emaciated phthisical patients.

If the immediate consequences be not fatal, the fever subsides into the same type which existed before perforation occurred. This is the hectic of phthisis, in which the pulse seldom sinks below 110, and is exacerbated in daily paroxysms. We are, however, led to believe, that if the opposite lung be not already the seat of tubercular deposition, or even if this be not in an advanced or progressive state, the phthisical hectic which attended the disease of the lung that has suffered perforation, is diminished by the supervention of pneumothorax. We have witnessed one case and heard of another in which the hectic pulse and night sweats could be traced to have actually ceased from this period. In both instances, it is true, the cessation was but temporary, but we had unequivocal evidence that their return was contemporaneous with the occurrence of disease in the opposite lung.

The foregoing is a detailed account of what are called the *rational* symptoms. Their study is of great importance in understanding the disease, and it must be acknowledged that several amongst them are valuable diagnostic signs. We proceed now to describe the *physical* signs. It would be a needless task, at the present day, to use much earnestness in insisting on the importance of these in the exploration of any thoracic disease, for it is fully recognised. We must remark, however, with respect to pneumothorax, that just in proportion as the practitioner has attained to a masterly facility in their application, will he be enabled to decide with certainty as to its presence or absence. The very existence of this affection in nosology is so intimately connected with its physical signs, that until these were discovered it lay still unnoticed, and correct notions on the subject advanced as they were developed and improved. Hippocrates laid the foundation for its future diagnosis by the practice of succussion, and had he pushed its application a little further, he must himself have arrived at its real signification, as it appears, from some of his remarks on its use, that he was partially aware of some of the conditions necessary for its production. Corvisart and Bayle, masters of percussion, had glimpses of its nature, and remarked its existence in the dead body. Laennec, whose merit in this instance was as great in perfecting and applying the other two signs as in adding his own famous discovery, was the first who detected it on the living body. He brought its diagnosis to perfection by assigning to the physical signs their value separately and in combination; and if any additional light be thrown on its history or symptoms since his time, even this must be ascribed almost wholly to the greater facility and confidence with which it is now recognised by the employment of these means. These considerations are sufficient to show the great importance which attaches to these physical signs in pneumothorax: upon them, in fact, rests its diagnosis, and he who is skilled in their application may truly pronounce upon this affection, which has remained for so many ages of medicine in obscurity, in as positive a manner (as Andral speaks of these principles applied to thoracic diseases in general) as the surgeon can "of the least complicated dislocation, or the simplest fracture." (Clinique Médicale, Avantpropos, p. 6, tome ii.)

a. Succussion.—Whenever air and fluid exist together in the sac of the pleura, if the trunk be shaken abruptly, the splash of the liquid against the walls of the thorax is often distinctly heard by the patient, or by any one who places their ear on or near the chest. There is no stronger evidence of pneumothorax than this sound, for it is only produced where both air and fluid are present; if either be absent, no splashing sound is heard.

In the writings of Hippocrates this method of exploration was taught as a means of ascertaining the existence of purulent matter in the pleura. Distinct directions are enjoined as to the manner of performing the succussion, and even observations added from which it is apparent that the author could estimate by this means the quantity of pus contained in the pleura: "Among the patients affected with empyema, those who produce most sound, when shaken by the shoulder

have less pus in the chest than those who yield less sound, and who are more flushed and breathless: in respect of those who do not yield any sound, but who have the nails livid and a great dyspnœa, they are full of pus, and their case is desperate." These remarks contain much truth, and implying as they do considerable acquaintance with the phenomena, it is a most remarkable circumstance that they did not conduct their author, or his admiring commentators for so many ages afterwards, to the knowledge of the real condition which they indicate. Laennec points out the reason why, while such close approximations as that quoted from Hippocrates appeared as it were to leave only another step to unfold the truth, they remained as far removed from it as ever until a very late period. It consisted in a fundamental error as to the natural state of the lungs and pleura. The early notions were a mass of confusion on this subject, but for the most part it was conceived that a vacuum existed in the thorax. This absurd hypothesis precluded the necessity for the presence of air to cause the sound of fluctuation, and being handed down from age to age prevented the truth from reaching the mind even of such men as Morgagni. It is obviously inferrible, from the quotation which Laennec makes from the latter, that this great pathologist believed that the fluid of an empyema was poured out into an empty space in the pleura, which, after a certain quantity of effusion, became filled. In the quotation which we now insert, this opinion is not left to inference, but alleged in the most explicit terms, and even adduced as the only way of explaining the sound of the fluid in a case of pneumothorax. Referring to the "stillicidium cadentis humoris," which we formerly quoted from him, Morgagni says, "Res non ita facilis explicatu iis *qui inter pulmones et thoracis parietes negant spatii quidquam intercedere; vera tamen, ut postmodum comprobavit humoris, in eo latere congesti, cum fluctuatio in agitatione corporis ab ipso, ab aliisque evidentissime percepta*," &c. (Prænot. Coac. ii. 432. Forbes's translation of Laennec, p. 507.) On such an hypothesis the sound of fluctuation should have been heard in every case of empyema, instead of being, as we now know it to be, confined solely to the case where this is combined with pneumothorax. It is very probable, then, that its abandonment is to be attributed to its having failed to detect simple empyema, which it could never have done. It is moreover certain, from the description, that the cases designated by Hippocrates as "full of pus," and which Morgagni would have embraced under those "qui ad summum pervenerunt," were cases of simple empyema, and it shows that, although these great physicians were prevented from seeing its true cause by a false hypothesis, they observed with accuracy and fidelity; as in such cases no sound of fluctuation is heard, the "*space being filled up*," as Morgagni said.

Thus this invaluable diagnostic fell into neglect; there is no evidence of its having been used after the time of the Asclepiades; and even the commentators appear to have esteemed it as useless, and to have alluded to it, as Laennec remarks, merely out of respect to Hippocrates. It was not revived till the true causes which produce it became fully explained, but since that period it has been ranked as one of the most infallible signs by which any internal disease can be recognised.

The Hippocratic method is still generally used in the employment of succussion. While the physician places his ear to the side of the thorax, an assistant shakes the patient smartly by the shoulders, and thus the dashing of the fluid is heard. It frequently happens that the patient is the first to call attention to it by mentioning that as often as he turns over in the bed he is sensible of this sound himself. It is felt by him on descending a stair, or, as we have known, when he makes a forward step with greater quickness than usual. Besides the little confidence which Morgagni placed in it as an indication, he objected to the Hippocratic method that many patients would not suffer willingly the concussion of the trunk. While this remark cannot have the effect which he intended, yet it is worthy of attention. Laennec denies that it is attended with any inconvenience, but in the cases in which we have seen it employed, a very considerable commotion was caused to the patient before the fluid could be heard. An intelligent man, who was under our care for a very long period, was accustomed to produce the fluctuation himself by making a jerking rotation of the trunk on the spinal column. He was enabled to produce the sound with much facility, and greatly preferred doing so himself in this manner to being succussed in the ordinary way by the hands of another. We can conceive that in certain cases such a method would be as impracticable as the former; we leave them both, therefore, at the option of the practitioner, who will of course choose that which causes least disturbance to the patient.

This fluctuation might be also produced by an enormous phthisical abscess half full of matter and air; but such a cavity as would be sufficient to give rise to it is scarcely ever met with, having occurred but once in the large experience of Laennec. There is also a possibility of being deceived as to the source of the fluctuation, if the stomach contain much flatus, and the patient has recently taken drink. The other physical signs will easily preclude the latter error; but its infinite rarity alone seems to be the only protection from the former.

b. Percussion and auscultation.—Laennec has demonstrated, from a review of the knowledge which Avenbrugger, Corvisart, and Bayle possessed on this subject, that percussion alone was insufficient for the diagnosis of pneumothorax. When the side affected is percussed, an unnaturally clear or tympanitic sound is returned, and if this coincide with dilatation of the same side, the evidence for pneumothorax is very strong. From these data Bayle was enabled to recognise it in the dead body in two or three cases; and doubtless, if its pathology had been understood in his time, he would have detected it from the same evidence on the living. But even in the hands of the most experienced master of percussion these signs might lead to a deep fallacy, for it might be thought that the clear-sounding side was in a healthy condition while the other was the seat of either pulmonary engorgement or a pleuritic effu

sion, which produced the comparatively dull sound; and as to the dilatation of the side, it is liable, when considered only in conjunction with percussion, to lead to the same error; that is, the dilated side might be mistaken for the sound, and the latter regarded as in the state of contraction which results from chronic pleurisy (See PLEURITIS); and again, the converse of this error is also possible, in which the contracted side should be mistaken for the sound side, and the latter considered as dilated and too resonant. That these difficulties of diagnosis from these means are not imaginary our own experience has convinced us as well as the warnings of Laennec, (Forbes's Translation, p. 497); they are, however, quite removed by adding to percussion the results of auscultation. On applying the stethoscope to the pneumothorax side, it is found that the respiration is as completely absent as if it was an empyema; but percussion has already proved that, instead of the perfectly dull sound, which a collection of liquid in the chest causes, we have now a preternatural clearness of sound, which two conditions, viz. nullity of respiration and clear sound on percussion, never coexist except in the case of air in the cavity of the thorax.

Although we have indicated the percussion sound of pneumothorax to be exceedingly clear and tympanitic, occasional deviations to a certain extent from this general rule are met with. It will be recollected that when pneumothorax takes place, the expansion of the air vesicles of the opposite lung becomes much increased from having to perform the compensatory respiration, and consequently the clearness on percussion of this side is simultaneously increased. This is one cause why the *contrast* on percussion is not so striking as might be anticipated, and it suggests how much more valuable this sign would be were it possible for us to contrast the sound of the *same side* before and after the period when pneumothorax was supposed to occur. Another circumstance which occasionally prevents the drum-like resonance peculiar to this affection from being produced, is the existence of partial adhesions which sometimes retain the lung in spots still in contact with the costal pleura. In the points corresponding to these the sound on percussion will still be dull, while the clearness will be perceptible in the intervening spaces. It is also to be remarked that, although we have laid down nullity of respiration as the rule, this is seldom absolute. Close attention will almost invariably discover a feeble bronchial sound at the root of the lung along the spinal column, which may sometimes lead the observer to imagine that he hears the puerile respiration of the opposite lung conveyed across the spine. But besides this, if there be any points of adhesion, they may cause a faint murmur to be heard. These adhesions may exist at any part of the lung, but as we have in a preceding part shown that they are very common at the summit, so we are not unfrequently enabled to discover, immediately under the clavicle or in the supraspinal region of the scapula, the sound of respiration generally of a cavernous character, and mixed with a single bubble of gargouillement. These latter signs may be considered as marking the remains of a cavity (see TUBERCULAR PHTHISIS), and this is sometimes confirmed by the coexistence of an obscure pectoriloquy.

The fluid which is contained in the cavity is recognised by these signs with the same facility as the air. By the absence of respiration we learn that the lung is now displaced by either fluid or air. This being established by auscultation, the results of percussion enable us to appreciate the space in the thorax which is occupied by the liquid and gaseous fluid respectively. As percussion is performed from above downwards, the tympanitic resonance is perceived to give place at a certain level to a total dulness of sound, and where this change abruptly occurs is the line of demarcation between the air and fluid. By marking from time to time the situation of this line, it is manifest that we can ascertain whether the proportion of the air and fluid remains stationary, or if either of them increase at the expense of the other. Finally, it may be instructive to examine their relations under changes of posture, to observe how the liquid obeys the law of gravity, and the tympanitic sound shifts as the air moves to occupy the space vacated by the heavier fluid. Such investigations furnish data from which an acute observer may form a conjecture as to the existence of adhesions, the size of the cavity, and even the amount of the compression sustained by the viscera; upon which points it may be of the highest importance to obtain any additional light, particularly if the idea of paracentesis be entertained.

The signs of pneumothorax derived from auscultation and percussion, so far described, are almost purely of a negative character; but even were the diagnosis necessarily confined to them, there is but one disease for which it could possibly be mistaken; this is emphysema of the lung, or dilatation of the air-cells, many of the characters of which are, however, so clearly distinguished from it, that it could only be confounded with it by a very inattentive examination. They resemble each other in the clear resonance which percussion gives out, and also in the negative results of auscultation. But the respiration is never totally absent in emphysema of the lung, as in pneumothorax; it is only much weakened, and is moreover accompanied by its peculiar râle, which strikingly opposes them. The history and general phenomena are quite distinct; the emphysema is always a chronic malady, and the patient is able to go about; although complaining much of difficulty of breathing, it is more because it interferes with his occupations than from the deadly anguish which overwhelms the patient in most cases of pneumothorax. If these considerations be not sufficiently convincing, the presence of pneumothorax (from perforation at least) may be decisively determined by succussion and the metallic tinkling.

The inventive genius of Laennec was not content with these negative results of auscultation. Apparently not long after he had laid the foundation of its diagnosis in these, his perseverance was enabled to add to them a positive sign, the *tintement métallique*. This is a metallic tinkling or ringing sound, heard in the pneumothorax cavity at intervals. It is discerned equally well by the naked ear or by means of the stethoscope, but to examine it accurately and to mark its limits, the

latter instrument must be employed. It is so accurately represented by the dropping of a pin into a large wine-glass, or touching gently a sonorous porcelain vase with a quill, that it may be recognised without the observer having previously heard it; by keeping this comparison in mind, having been once heard, it is always remembered.

The metallic tinkling is audible during coughing, speaking, and sometimes during respiration, or it might be more correct to say after these actions. Besides this, it is often heard independently of these, observing a certain periodicity, and finer in its tone. That the finer tone which we have just alluded to is the echo caused by the occasional fall of a single drop of fluid from the summit of the cavity on the surface of the liquid, we only require to imitate it by letting fall into a large wide-mouthed bottle, one-third full of water, one drop of any liquid, to be fully convinced. This variety of the tinkling is explained in this manner by Laennec, who has also proved demonstratively that the sort which results from speaking, coughing, and inspiration, is produced by the air entering through a fistula into the pneumothorax cavity. He did not announce more particularly its proximate cause, and where this master did not speak, it might become us to be silent. We may state, however, without presumption, that we never had any hesitation in explaining this variety of the tintement on the same principles as the other. It appears to us to be manifestly the echo of the air forced into the cavity reverberating against its hollow parietes, and that the sound is more particularly caused by the bursting of minute air-bubbles at the orifice of the fistula, formed as the air traverses the latter, by its entanglement with mucus. It is more clearly audible in proportion as the cavity is empty of fluid; but its distinctness and loudness are chiefly dependent on the size of the fistulous communication. We have been enabled to follow the gradual narrowing of the latter by the diminution of the tinkling in one remarkable case. It became so minute that it was by the greatest stretch of attention scarcely perceptible on respiration, and at length became inaudible, but it still persisted on speaking and coughing. At an after period the whole train of symptoms became exacerbated, and the tinkling was again manifest on respiration; and by degrees, as the malady grew worse, it increased to a louder and graver pitch than ever. This is indeed the ordinary change which it undergoes; in most cases the fistulous orifice rapidly enlarging in size, the tintement is heard more and more plainly on respiration, and at length it becomes so deepened in tone as to assume quite a different character.

To the metallic tinkling altered thus by the deepening of its sound, the name of *bourdonnement amphorique** has been given. It is so called because it exactly resembles the sound produced by blowing into a decanter or large bottle. When this sound becomes evident, it is a sure indication that the fistula is growing larger, and consequently that the case is more hopeless.

In exploring for the metallic tinkling, there is a source of fallacy which the physician should be aware of. When the stomach is flatulent, it lies high under the false ribs, and if in this state the patient has lately taken drink, the tinkling may be produced in the stomach, and lead the observer to think he hears it in the chest. On the other hand, an incident occurred to the writer of this article, which shows that this source of deception may be held too strongly in view. In examining a case which at first view he had imagined was empyema, the tinkling was evidently perceived; but finding the epigastrium tympanitic, it was disregarded, from the conception that it was produced in the stomach. On the second or third examination the sound was again heard, and now recognized to be the true metallic tinkling.

The only other condition besides pneumothorax which can give rise to this sign is the existence of a vast phthisical abscess, such as also produces the sound of fluctuation. Laennec relates its occurrence in a phthisical abscess of such a size that the whole lung was nearly involved in it; but such instances are so infinitely rare that they will never embarrass the diagnosis.

The production of the metallic tinkling in a phthisical cavity, we would remark, is a circumstance quite inconsistent with the views on the subject which Mr. Guthrie has lately published. This gentleman states that Laennec, and all who hold, with him, that it "depends entirely on the passage of air through a hole in the lung into the cavity of the thorax," were mistaken; and in opposition to this he maintains that for its production the air of the cavity must necessarily be compressed. "I do not," says Mr. Guthrie, (London Med. and Surg. Journ. for Jan. 12, 1833, p. 477,) "deny the facts of the air, the hole in the lung, or the fluid; but I believe that, to produce the sound of the Jew's-harp (the metallic tinkling,) the air in the cavity must be greatly compressed, and that it essentially depends upon it." That this latter opinion is unfounded, its occurrence in large tubercular cavities, which has been observed by most who are much conversant with phthisical auscultation, sufficiently proves. In such the air can suffer no compression. It is besides well known to exist after the operation for empyema; and we have never heard it more audible than in a case of pneumothorax caused by the bursting of an anthrax of the intercostal spaces into the pleura, in which the external fistula remained open.

We have now concluded the account of the diagnosis, but as we have been necessarily diffuse on some of the points, we think it may not be superfluous here to recapitulate, so as to give at a glance the principal diagnostic signs. By subjoining to each a word of valuation, the reader will be able to calculate the amount of evidence implied by the presence of any one of them.

1. The sensation of something giving way in the chest, and of air entering the pleural cavity.—Very valuable, but often absent or unnoticed.

* We would gladly use English words, but cannot devise any that would justly anglicise the above; we have, therefore, thought it better to leave the expression which the discoverer applied. Nothing can be better than metallic tinkling, but it appears to us that "utricular buzzing," which is used in the valuable translation of Dr. Forbes, although a correct synonym, is scarcely less foreign than the original.

2. In a phthisical individual the sudden supervention of overwhelming dyspnœa and pain.—Rarely absent, therefore very valuable; still more so if succeeding last sign.
3. Comparison of auscultation and percussion. Nullity of respiration over one side, together with tympanitic clearness of sound, which below terminates abruptly in complete dulness.—If accurately established, amounting to positive certainty, but sometimes not easy to establish. Ægophony rare.
4. Fluctuation on succussion.—Positive certainty, but should be unquestionably verified.
5. Metallic tinkling.—Positive certainty, but should be unquestionably verified.

Prognosis and treatment. On casting our regards back on the pathology of this affection, we cannot be astonished at any thing which experience can teach us, as to the rapidity and certainty with which it is followed by a fatal result. When we consider the prognosis of phthisis, and add to this the aggravating circumstances of perforation and acute inflammation of the pleura, together with the simultaneous privation of the function of one lung, the consequences will appear to be so inevitable and immediate, that our review of its pathology and symptoms may seem to be a dissertation on a nice point of morbid anatomy and diagnosis, or only useful so far as an acquaintance with it may prevent the physician from being taken by surprise by the supervention of its fearful indications in a case of phthisis. And, indeed, if all knowledge were useless that did not immediately lead to practical benefit, this would be in a measure true; for it must be confessed that at present it does little more than unfold to us how soon we may expect a period to be put to the patient's sufferings. The result of Laennec's experience of it is more fairly drawn from the statement which he makes for the purpose of contrasting it with emphysema of the lungs, than where he specially speaks of its prognosis. "The effusion of air," he says, "comes on suddenly, and cannot exist for any length of time without giving rise to severe symptoms, and even death. I have never seen pneumothorax in any person who was not confined to bed." (Forbes's Trans. p. 499.) Louis only speaks of the result with a view of calculating the time which elapses between the period of perforation and death. (Recherches sur la Phthisie, p. 487.) Dr. Stokes relates his case, which lasted five months, as the longest at that time on record; (Trans. Association, &c.;) and in upwards of twenty cases witnessed by Dr. Townsend, none, we believe, lasted so long a period. In Louis's seven cases the fatal termination took place at intervals of from sixteen hours to thirty-six days after the perforation occurred; and this author adds, "it is difficult to give an account of the circumstances which produce this difference, and it is in vain to seek for the explanation in the greater or less strength of the patients at the time that the accident took place." (*Louis*, op. cit.)

The only question, then, which the prognosis admits of is, whether recovery in pneumothorax from perforation by tubercle is barely possible. Laennec, arguing from his observation of the cicatrisation of tubercular cavities, is of opinion that it must not be regarded as impossible even in the severest cases. This opinion is shared by some others, but it is to be regretted that the few facts which are produced in its favour are drawn from the older writers, who were ignorant of its production in this manner. Some of them were evidently, at first, cases of empyema, which, by opening into the lung, gave rise to the pneumothorax: and we believe that most pathologists consider even the case related by Laennec, in which the pneumothorax existed for six years, was of this nature. But the progress of a case detailed in the third number of the Dublin Journal of Medical and Chemical Science (which has been more than once adverted to in this article) has induced us to believe that this case of Laennec and some others may probably have resulted from tubercular perforation, and to adopt his opinion as to the possibility of recovery. In this case the individual lived a year and a half after the establishment of the fistula, during which period the dilated side became contracted, but ultimately resumed its former dilatation. The patient's general health and strength became so much improved as to permit him to work as a bricklayer for some months of this period, but this labour exhausted him very much. His own imprudent perseverance in working under exposure produced an attack of severe and general pleuropneumony in the opposite side, which his extraordinary vigour enabled him to outlive, but he ultimately sank under the effects of repeated acute inflammation of the other lung as well as of the pneumothorax sac. The other medical men who saw it with the author agreed with him in thinking that this case might have lasted for a very long time; in fact that the contraction of the side, the improvement of health, and the disappearance of the tintement metallique indicated a spontaneous attempt at cure which was counteracted by the reckless neglect of proper caution on the part of the patient. The contemplation of this case, with some observations suggested by it, has, as we have said, induced us to admit the possibility of recovery, which, however, we by no means wish to inculcate in a positive manner: before this can be done by any one, a more enlarged experience must be possessed, and the observer, who is desirous of deciding the question by facts, has to set out with the melancholy knowledge that not one case proved by auscultation to have been of this nature is on record in which ultimate recovery took place.*

* For our opinion, as above stated, we have not adduced arguments where facts are wanting; but a consideration which weighed with us much, suggested by the above case, may be mentioned here. If the first effects of the perforation be outlived, (which is rare,) it does not appear that a worse condition exists in pneumothorax than in empyema, *provided the opposite lung remains free from tubercles.* It may be objected that there remains the tubercular state of the compressed lung. It is true; but we believe that the conditions which make tubercles so fatally progressive in the lung are absent in the latter; we allude to its constant motion and its great supply of blood. The motion and consequent friction which the act of respiration constantly maintains around a tubercle, appear to us to be a principal cause of the irritation which it produces, and consequently of the increase of its own bulk. Developed

The resources of the healing art, it will be anticipated, can contribute little of a positive nature, if any thing, to promote a cure in this calamitous affection. Yet, as in all such extremities the aid of the medical man will be eagerly sought, he should be prepared to do something, although he may regard it as ultimately certain to triumph over human efforts. Few cases will present themselves where some symptoms which aggravate the patient's sufferings may not be removed or alleviated by appropriate means. Proud science may draw back from what seems to be beyond her realm, but the physician has higher instincts to obey and duties to perform here as in other hopeless diseases, in attempting even the mitigation of the pain and anguish which science informs him he cannot altogether remove; and this reflection may be added, that where such motives actuate him to exertion, he is seldom left entirely without means, and never without the satisfaction which obedience to them brings.

We would consider, then, whether any thing can be done to allay the urgency of the symptoms by which the patient is so usually oppressed immediately on the occurrence of this species of pneumothorax; the dreadful dyspnœa, sinking, and pain. We find on this subject no assistance from books, for as the affection itself has been but recently clearly understood, its detection at this early period has been extremely rare; and this, we think, should suggest to all practitioners having the care of phthisical individuals, the utility of keeping in mind their liability to this event, in order to be able to afford assistance with promptitude should it occur. The indications for practice appear to be sufficiently clear. If it has supervened in the last stage of phthisis, when the patient is much emaciated, and already nearly spent by hectic, the treatment must be little energetic. Leeches should be applied in small number to the part where the pleuritic pain is most acute. Afterwards a fomentation of strong decoction of poppy heads, or an anodyne poultice should be used, and in twelve hours another application of leeches might be had recourse to with advantage. The exhibition of a strong narcotic internally will also tend to relieve the dyspnœa as well as the pain, for this class of medicines has the power of diminishing the sensation of want of respiration as well as of lulling the general sensibility of the brain. The use of anodynes may have probably been habitual with the patient before this occurrence, and in this case the usual dose should be increased. We need not specify the particular preparation, but may mention that the "acetum opii" and the "black drop" are often preferred by phthisical patients, and that it is prudent to vary by times from one preparation to another, by which means narcotics do not lose their effect so soon, when the dose is not augmented. If the individual be yet in the very early stages before the perforation, then it would appear to be a very rational proceeding to bleed him copiously, and to treat him with an especial regard to the pleuritis, which speedily ensues. A large bleeding seems to be a very proper measure in such a case for the purpose of diminishing the mass of blood in the circulation; by this means the opposite lung will be less oppressed by the additional influx which takes place from the compressed side;* and this might be confidently expected to alleviate the aggravated dyspnœa of which the latter condition is a principal cause. The leeches can be used here in large number, and the anodyne will follow the bleeding with great propriety, co-operating to the same effect. An assiduous application of these remedies, and watching their effects, might do much to relieve the urgency of these symptoms, which, if they be not by some means arrested, grow hourly worse.

But cases will occur where these means will be insufficient to prevent the dyspnœa from increasing to such a pitch as to threaten imminent suffocation, and then the operation of paracentesis is the only resource by which a longer space may be added to the life of the patient. The escape of the air effected by this means is almost always followed by great relief of the symptoms, abatement of the dyspnœa, and lowering of the pulse. This is only temporary. After a period, which is seldom long, although different in each case, the patient sinks, being only saved from suffocation to die of the consequences of the operation. It is, however, justified in such extreme cases by the prolongation of life which it effects, and the alleviation of that most distressing of all suffering which results from extreme dyspnœa.

In such a case, where the only question is whether life shall be allowed to be extinguished, the medical man has no alternative to balance; but if the urgent dyspnœa and pleuritic symptoms have already passed over without destroying the patient, and the case has attained a certain degree of chronicity, is paracentesis advisable? This question is at once set at rest if the existence of tubercles be proved in the other lung, as in such a case not a shadow of hope could be entertained of its success. Since Munro and Hewson advised the operation, it has been occasionally advocated without discriminating between the varieties of pneumothorax; but although the latter of these writers made a sharp conjecture on the subject, it is evident that neither of them had any adequate notions as to that species of which we treat. The chief, if not the only authority by which its performance in pneumothorax from such an internal cause can be supported, is a passage in Riolan, and the case in which Munro advised it. On referring to the former it is impossible to form an idea of what species of it his observations include;

in organs whose function does not submit them to motion or friction, their progress is incomparably slower than in the lung. Moreover, the great quantity of blood which circulates in this organ, probably contributes to its rapid progression. We would now observe, that in the lung compressed by pneumothorax, the influence of these causes is absent, as it lies against the spine in a state of nearly perfect quiescence, and of comparative anæmia. We would remark, also, that in the above case the hectic sweats ceased almost entirely from the time of the perforation, and we refer to its dissection for some particulars of the compressed lung.

* We find this argument used by Andral in recommending copious bleedings in the case of pleuritic effusion. "Lorsque l'épanchement existe, on doit encore avoir recours hardiment aux saignées, dans le double but de s'opposer aux progrès ultérieurs de l'inflammation, et de diminuer la quantité du sang, qui dans un temps donné doit traverser le poumon comprimé." Clin. Méd. t. ii. p. 582.

but it is very plain that he speaks only of the present relief which paracentesis procured, and not of the ultimate consequences. The following are his words: "Interdum flatus tam violenter distendit pulmones, ut præfocationem, adferat, ni succurratur aperto thorace per ipsam paracentesim, quod sæpius factitatum *Parisiis*, magno ægrorum emolumento, et thoracis levatione, etiamsi aquæ nullæ effluxerunt, sed flatus cum violentiâ displosus." (Riolan, Encheiridion Anatomicum. Lib. iii. cap. 2.—Med. Obs. & Enq. p. 394.) Monro's case, in which the operation was successful, is recorded with considerable accuracy; and we think that any one conversant with those matters, who examines it, will at once deny that it belongs to this class; it seemed, in fact, very probable that the air escaped into the chest by the rupture of some of these distended subpleural vesicles, which are not uncommon in emphysema of the lung, under which apparently the patient laboured for many years. (See Halliday on Emphysema, p. 49.) Universal experience of its failure, as well as the great weight of authority, is against the operation; for no case has recovered after it, of this variety of pneumothorax, since it has been possible to recognise it by auscultation. Its failure appears to have for its cause the readiness to take on a bad inflammation, which the false membrane and pleura possess in this species, in consequence of which it is very common to find a gangrenous state of these membranes occurring after the wound, propagated originally from its edges. Notwithstanding its not having succeeded hitherto, there is still a decided leaning to perform the operation whenever a case occurs. This in some measure is caused by the fact, that the old ideas which connected fluctuation and simple empyema are not yet perfectly exploded, and partly from the too generally applied notion, "melius est anceps experiri quam nullum,"—an adage which is sometimes erroneous, and founded on a forgetfulness of the part which nature takes in the removal of morbid action. The writer confesses it to be his own opinion that the possibility of cure which he has above professed to believe in, lies not in the appliances of art, but in the operations of nature.*

This terminates the subject of pneumothorax from perforation of the lung by a tubercular abscess. We have purposely devoted the bulk of this article to the consideration of this one species for the convenience of arrangement, as well as because it is incomparably more frequent than the whole of the other varieties. To have discussed the latter separately would have involved us in a mass of tedious repetitions; and it seems certain that he who is acquainted with the species which we have chosen for its description, can be at no loss fully to comprehend its pathology and diagnosis, should he meet with it arising from other sources; or at least we trust that the foregoing account of it will place him in such a position that he will be enabled to investigate them for himself. In conclusion, we shall now briefly mention the other methods by which authors have described it to arise.

Pneumothorax from gaseous secretion of the pleura.—The pleura, according to Laennec, in very rare cases takes on the secretion of air like the other serous membranes. This may take place singly, or the elastic fluid may accompany an aqueous or puriform effusion. This variety has not been decidedly established by the observation of other pathologists since the time of Laennec, and we record its existence merely on his authority, and on that of Andral, who relates a case of it, in which, however, this origin was not unquestionably proved. (Clinique Méd. t. ii. p. 512.)

Pneumothorax from the opening of an empyema into the lung.—The bursting of an empyema into the lung is not a very unfrequent occurrence; and yet this is an extremely rare source of pneumothorax. When it takes its origin in this way, the empyema has generally been circumscribed. This variety of pneumothorax is that in which the operation is fairly entertained (See Empyema); and we believe that the cases which recovered after it, where it was proved by the fluctuation to have existed, must be referred to it. We allude to the remarkable cases of Dr. Archer (Trans. Dublin Association) and Dr. Hawthorne, (Edinb. Med. and Surg. Journal, No. 61,) &c.

Pneumothorax from gangrenous perforation, and from rupture of the pleura in emphysema of the lung.—The first of these cases has been occasionally remarked, but the latter is extremely rare. Monro's case of successful operation was, as we have before stated, very probably of this nature. In it the rupture took place during a fit of coughing, and it was succeeded by general emphysema of the cellular tissue as well as pneumothorax. Laennec thought that he observed its origin from this cause in one case.

Pneumothorax from lesions of the thoracic parietes.—We should mention under this head, 1st, that consequent on penetrating wounds and lacerations of the lung by fractured ribs, called hitherto by surgeons emphysema thoracis. Dr. Hennen remarks that the fears which exist as to its arising from these causes are greatly exaggerated, as it is in fact a very rare occurrence in military surgery. (Hennen's Military Surgery, third edition, p. 380.) 2nd. Where it is consequent on the opening of an anthrax or abscess through the intercostal spaces. Of the former we witnessed an interesting case in the Meath Hospital, in which all the phenomena were remarkably perfect. To the latter belongs the singular case described by Dr. Duncan, in which a diffuse abscess spread from the arm to the chest, and penetrated the costal pleura and lung, upon which a circumscribed pneumothorax formed, communicating with the external abscess, and producing elastic tumours on the side. (Trans. Med. Chirurg. Society of Edinb.) 3rd. The species which succeeds to the evacuation of the purulent matter after the operation of empyema. This is an invariable consequence, but we believe that its prejudicial effects are too much insisted upon, as patients sometimes live many years with a fistulous opening in the side, and enjoy a tolerable state of

* If ever the perfecting of diagnosis shall arrive at distinguishing the cases where pneumothorax is caused by the bursting of a single tubercle, or of a small mass, we conceive that in such a case the operation may be yet practised with success.

health. The case of longest duration which we are aware of is that related by Dr. Otto, in which the individual daily discharged a small quantity of purulent matter through the aperture formed by the operation for seventeen years, and was enabled for nearly that period to take part in social life. (Acta Nova Reg. Soc. Med. Havniensis, vol. vii. p. 79.)

JAMES HOUGHTON.

POISONING.—See TOXICOLOGY.

POLYPUS OF THE UTERUS.—See UTERUS, DISEASES OF.

PORRIGO.—Porrigo is the generic appellation for several pustular diseases affecting the scalp chiefly, but occasionally other parts of the body, agreeing less in their symptoms than the species of almost any other of the genera of cutaneous diseases in the classifications of writers. It is synonymous with the *tinea* of Avicenna and various authors.

Porrigo is defined by Bateman, "an eruption of straw-coloured pustules, concreting into yellow or brownish crusts or cellular scabs;" but this definition accords with three only of the species usually arranged in this genus; and, indeed, the genus actually comprehends three diseased states of skin, differing not only in their symptoms, but requiring distinct modes of treatment. But as little advantage perhaps would be derived from an alteration of arrangement, or the division of this genus into three distinct genera, we propose to arrange the species so as to bring together those that accord, and separate others the characters of which are evidently distinct. They may be all arranged under the three following sections.

SECT. I. PORRIGO, *true porriginous eruption*, comprehending—

Species 1. *P. larvalis;*
2. *P. lupinosa;*
3. *P. favosa.*

II. ECZEMATOUS PORRIGO.
4. *P. furfurans.*

III. ANOMALOUS PORRIGO.
5. *P. scutulata;*
6. *P. decalvans.*

I. **True Porriginous Eruptions.** — These are characterized by the pustules assuming those forms which have been denominated *favus* and *achor*, and by being unaccompanied with fever. The different forms may be regarded rather as varieties than distinct species, as they sometimes exist simultaneously on the same person. They affect both sexes and all ages, but are most frequently observed in infancy and youth. In many instances it is difficult to trace them to any peculiar predisposition; but in general they may be referred to some deranged condition of the digestive organs, to improper food, and occasionally to depressing passions. None of the true porriginous eruptions are contagious, nor does the treatment applicable to all of them materially differ.

Species 1. *Porrigo larvalis; milk scall or crust.*—This species of porrigo appears on the forehead or cheeks, in the form of small, yellowish, white, superficial pustules, upon a red surface, in irregular groups. On breaking, they pour out a greenish-yellow fluid, which concretes into thin lamellated scabs, usually of a brownish hue. New groups of pustules form in the vicinity of those that have broken; these break, and, as the former, pour out their fluid, which encrusts in its turn; whilst the old scabs are thickened and extended by the fluid continuing to ooze out from below them, so that by degrees the whole of the face becomes covered by these scabs, as if with a mask; thence the specific term *larvalis*. At this time the crusts exhale a rank peculiar odour, which Alibert likens to sour putrid milk. The eruption varies in severity: sometimes the inflammation is intense, the exuded humour very abundant, and so acrid as to excoriate the cheeks and other parts; at other times it is moderate in quantity and mild in quality; the pustules are few, slow, and successive in their development, and the crusts thin and dry. Besides the forehead and cheeks, patches appear behind the ears, around the mouth, and upon the chin, yet they rarely appear upon the nose and eyebrows. Small patches occasionally break out about the neck and breast, and sometimes even on the extremities. When they rise upon the hairy scalp they assume a chronic character; the bulbs of the hairs sometimes inflame, and baldness, temporary or permanent, may be the result. In whatever part the eruption is seated, it is accompanied with itching, sometimes with stinging pains, which are more severe, the younger the patient is, and in infants not only greatly disturb the natural sleep, but derange the digestive function. This is particularly the case in plethoric children, and especially when the eruption spreads over much of the neck and breast. The eyes and eyelids are often inflamed, and discharge a purulent matter; when the discharge on the scalp is absorbed, the parotid glands swell. In strumous and highly irritable subjects the mesenteric glands also inflame, and marasmus, diarrhœa, and hectic may supervene and destroy the patient. But this aggravation of the disease is a rare occurrence.

When the disease is yielding, whether spontaneously or to remedies, the pustules form more slowly, exude less, and the crusts fall off and are not renewed, but they leave behind them a red, tender cuticle, which is sometimes marked with deep lines, and occasionally exfoliates several times. Sometimes it appears as if about to yield, and then returns with greater severity. In this manner we have seen it vary during the whole period of dentition, and yet, unless the nails have been much at work, no cicatrices remain.

This species of porrigo is not contagious; but in a case mentioned by Alibert, in which an infant was inoculated with it, the disease was taken. It occurs in infants during the cutting of the first teeth, and also in children during the second dentition. We have never been able to trace it to any state of the breast milk when it appears in infants, but in every instance the stomach is in a very irritable state, and much acid is present in it. We have been able to trace it to the too free use of accescent food, such as fruit-tarts and puddings, sugar, and various articles of confectionary into which it enters, in children of full and gross habits of body. Rayer says that it is less frequent in the Parisian hospitals than the porrigo *favosa*, the proportion being as seventy-one to nine hundred and eight.

The disease most likely to be confounded with

porrigo *larvalis* is porrigo *favosa;* but to careful observers the circular depressed crusts of the latter readily distinguish it from the former. None of the other species of porrigo, except porrigo *furfurans*, is likely to be mistaken for it; but in porrigo *furfurans* the crusts dry and become very hard and greyish, which distinguish it.

In general the disease runs its course without danger, but, as we have already stated, the mesenteric glands may be in a diseased condition, in which case it becomes formidable, and may induce diarrhœa, marasmus, hectic, and thus prove fatal. The sudden cessation or repulsion of the discharge is also said to indicate an increase of some deeper-seated disease; but our experience has not led us to form such a conclusion. We concur in the opinion of Dr. Underwood, (Treatise on the Diseases of Children, 8th edit.,) that infants who suffer much from the milk crust are always healthy in other respects, and cut their teeth remarkably well. Dr. Starck (Starck's Diss. de Crusta Lactea Infantum, &c.) affirms that the prognosis is always favourable when the odour of the urine resembles that of the cat. We have not seen this remark verified; indeed, unless the disease occur in very young, ill-fed, and badly nursed children, or in those of an hereditary strumous constitution, our prognosis may always be favourable.

Porrigo *larvalis* requires both constitutional and local treatment.

When the disease appears in infants at the breast or during the first dentition, it is essential to allay the general irritability of the mucous membrane, which is the source of the acescent state of the stomach; and as soon as that is accomplished, to aid the general powers of the system by mild tonics. For answering the first of these indications we have seen much benefit derived from the hydrargyrum cum creta, in doses of gr. iii. to gr. vi. given night and morning; or in older children, when the mesenteric glands were enlarged, and the abdomen was tense and tumid, from calomel, in doses of one-tenth of a grain combined with one-fourth of a grain of ipecacuanha and half a grain of the powder of conium, given every eighth hour for a week. For fulfilling the second nothing answers so well as a combination of carbonate of soda, powder of calumba, and rhubarb, in doses proportioned to the age of the child and other circumstances, given twice or three times a day. Under such a plan of constitutional treatment we have witnessed the disease to yield in a very short time without any local applications except those which cleanliness requires. We have had no occasion to employ sarsaparilla, cinchona bark, the rumex *aquaticus*, nor the viola *tricolor* recommended by Dr. Starck. (Ibid.) During dentition the warm bath at bedtime is highly salutary, especially when the itching is so troublesome as to interrupt the sleep of the little patient. Nothing is more important than to examine the state of the milk: if this be thick, the nurse should either be changed, or her allowance of porter, animal food, and other stimulant nutriment should be diminished. If the infant be undergoing the uncertain experiment of being brought up by hand, the food should consist solely of milk diluted with an equal quantity of barley-gruel, and sweetened slightly with lump sugar. The quantity should be moderate, and any thing like voracious appetite in the child repressed.

In children of more advanced age, during the second dentition, when the pulse is quick and full, the face flushed, and the nights restless, it may be necessary to apply a few leeches either behind the ears or under the angle of the jaw; and in very obstinate cases to apply a blister on the nape of the neck, or between the shoulders, and keep it discharging for ten or twelve days. Gentle aperients, merely to regulate the bowels, are necessary, but we have never seen any advantage derived from a course of purging.

With regard to local applications, if the eruption occupy the scalp, it is scarcely requisite to say that the hair must be removed by scissors, for it seldom admits of being shaved; after which the separation of the crusts should be aided by a dressing of the oxide of zinc or the subacetate of lead-ointment on lint, covered with an emollient poultice. If the discharge be considerable and very acrid, the denuded surface should be washed with a solution of ʒii. of bicarbonate of soda in *f.*ʒviii. of bitter almond emulsion, or of milk with the addition of *f.*ʒss of hydrocyanic acid. In very young children, however, it is advisable to leave out the hydrocyanic acid. As soon as the local irritation is subdued, if a return to the healthy state of the scalp seems to be retarded only by the crusts becoming dry, hard, and adherent, their separation and cicatrization are facilitated by the unguentum hydrargyri nitratis, diluted with six or seven parts of lard. We have never met with a case in which lotions of the hydro-sulphuret of potassa or sulphureous baths were required.

In conclusion we may remark that we are acquainted with no eruptive disease in which there is so complete an obliteration of every thing that could indicate the existence of the previous eruption after the crusts fall; and in none have we perceived less mischief to result from checking the eruption.

2. *Porrigo lupinosa; lupine scall.*—This species of porrigo is distinguished by the *achores*, which arise in small separate clusters, forming when they break circular scabs of a yellowish white colour, set deeply in the skin, with a central indentation or depression, sometimes containing a white, scaly powder. When seated on the scalp or on the temples, they acquire nearly the size of a sixpence, and there is sometimes an intervening thin white incrustation, which exfoliates, or occasionally forms an elevated crustaceous covering. The eruption sometimes displays itself on the shoulders, the thorax, the abdomen, and the extremities; but in these places the scabs never attain to the size which they do on the scalp. The eruption exhales an offensive odour, not unlike that of mice; it affords a harbour for pediculi in the crevices of the crusts; and when the acrid discharge is absorbed, the cervical glands swell; whilst long-protracted cases terminate in baldness. When left to itself, the disease is very long before it wears itself out, and even under proper treatment it is tedious of cure.

It is not contagious; and it is the least frequent

of all the species of porrigo. Its predisposing cause seems to be a low state of the habit, resulting from the miseries attendant on poverty.

The treatment of porrigo *lupinosa* consists chiefly in the application of emollient poultices, and soap and warm water; the mechanical removal of the crusts; and, after this is effected, the assiduous use of an ointment made with two drachms of the finely powdered seeds of the cocculus Indicus and one ounce of lard. In very obstinate cases, the hard crusts may be touched with diluted sulphuric or muriatic acid, or treated with a lotion made with *liquoris potassæ* ℥j, *olivæ olei* ℥ij, *aquæ* ℥j. When the crusts are removed, and the surface appears red and covered with numerous small ulcers, exuding a viscid, fetid, yellowish fluid, the diluted ointment of the nitrate of mercury is the best application to assist cicatrization, and complete the cure.

3. *Porrigo favosa; honeycomb scall.*—The eruption in this species of porrigo consists of small, flat, soft, straw-coloured pustules, termed *favi*, generally distinct, with an irregular edge, and bounded by a slight inflammation. The scalp is the chief seat of the eruption, but it sometimes occupies the forehead, the temples, the chin, the space behind the ears, the eyebrows, and occasionally it extends to the trunk and the extremities. When it appears on the scalp, the pustules are small, not very distinct to the naked eye, and the minute drop of yellow fluid which they contain does not escape, but dries within them, and acquires a deeper yellow colour, and is very adherent. The pustules, although they are usually distinct, sometimes appear in groups, and become confluent. When distinct, they are usually on elevated bases, and each is frequently traversed by a hair. In whatever manner they appear, they are always more or less accompanied with itching. If the crusts be removed by poultices, or by any lotion, they do not return, the formation of new pustules being necessary for that purpose. When the disease is left to itself the crusts are very adhesive, and remain in a dry, white, and brittle state, sometimes for months and even years. Sometimes as they assume this character in one place, fresh pustules appear in another. The hair separates with the greatest ease, sometimes leaving the part permanently bald. As the disease proceeds, if great care be not taken to keep the parts clean, pediculi harbour in the crusts, the itching augments to an intolerable degree, and the eruption exhales a most offensive odour. The excoriated surfaces, after the crusts are removed, exude a fetid reddish fluid, which concretes into irregular crusts. Occasionally they cause small subcutaneous abscesses and lymphatic swellings in the neck, which slowly suppurate; the axillary glands are affected when the eruption appears on the upper part of the trunk.

It is probable that the reticular tissue is the seat of the disease; although, owing to the bulbs of the hair becoming affected in long-standing cases, it has been supposed to originate there. It rarely happens that the hairs are detached without being diseased. The duration of the disease is uncertain.

Porrigo *favosa* is asserted to be contagious; because, owing to the acrimony of the discharge, it causes inflammation and scabbing on any sound part with which a diseased part comes in contact; as for instance the breast with the chin, or the hands and arms with the face in young children. The breast of the nurse may become affected in the same manner. It occurs at all seasons of the year, and in both sexes; but it is more common in infancy and childhood. The strumous diathesis, bad nourishment and poor clothing; damp, ill-ventilated houses, prisons, and the miseries of poverty in all their forms, may be regarded as its predisposing causes.

This species of porrigo may be readily confounded with porrigo *furfurans;* but as the pustules are found on different parts of the body in every stage of their progress, it is easily recognized. When the disease is of long standing, the hairs are destroyed on the affected parts of the scalp.

[It has been affirmed of late that the yellow substance, which constitutes the crusts of this affection, is an organic growth of simple structure bearing a marked resemblance to the vegetable bodies, collectively called *mould.* They have been examined by Remak, Schönlein, Fuchs, and Langenbeck, and Gruby, the last of whom states, that the crusts are made up of aggregated *mycodermata.* It is very questionable, however, whether these mycodermata be really vegetable; and it is certainly far more probable, that they are very simple animal growths.—(E. Wilson, *on Diseases of the Skin,* Amer. edit. p. 322, Philad. 1843.)]

Continental writers assert that porrigo favosa requires little more than local remedies; but we have seen no case of the disease in which it was not easy to trace it to some morbid condition of the system. For this reason a gentle alterative course is required, care being taken at the same time to regulate the diet and exercise. The former should consist chiefly of light animal food, with milk and farinaceous preparations; the latter should be regular, but never carried to fatigue; and when the tepid bath can be employed, which is always more or less serviceable, the exercise, in dry and temperate weather, should be taken immediately after using it. If the habit be decidedly strumous, the glandular affections severe, and much emaciation has taken place, tonics will be found to be necessary. The chalybeates are the most useful, and none possesses more power in such cases than the hydriodate of iron, given in doses of from one grain to three grains in a large quantity of water three times a day. The sulphate of quinia and the muriate of baryta have also been advantageously administered. In young children we have seen much benefit derived from the hydrargyrum cum creta, given every night in doses proportionate to the age of the patient; with a combination of cascarilla and subcarbonate of soda, in full doses, given three times a day. In adults a mild course of Plummer's pill with sarsaparilla is occasionally requisite, in cases of long standing which have resisted the usual mode of treatment.

With respect to local remedies, the first object is to free the scalp as much as possible from the crusts, and to subdue topical inflammation. This is accomplished by cutting the hair as short as

possible, or by shaving the scalp if the eruption admit of it; daily ablution with hot water and soap; and when the crusts are dry and very adhesive, the application of poultices. After the surface is pretty well cleared, an ointment containing equal quantities of the unguentum oxidi zinci and unguentum hydrargyri precipitati albi may be applied to the inflamed parts; or if the inflammation be moderate, the unguentum hydrargyri nitratis will answer better. The combination of the tar ointment, diluted with two parts of lard, and one part of sulphur, forms a useful application when the crusts are very adhesive; but the pitch-cap, which was formerly much employed, is apt to excite a highly inflammatory state of the scalp, and a considerable degree of symptomatic fever, consequently it should be used with caution. In addition to these topical applications, much advantage has been derived from the introduction of a seton in the nape of the neck or in the arm; indeed we have rarely witnessed the most obstinate cases resist the beneficial influence of such a drain continued for a month or six weeks.

Of all the local methods of treatment, that pursued by two brothers of the name of Mahon, in the Parisian hospitals, has been found the most efficacious; and therefore we shall give a brief sketch of it. The hair is first cut, so as to leave it throughout about two inches long; the crusts are next cleared away as completely as can be done by the aid of linseed-meal poultices and soap and water, a part of the treatment which occupies from four to five days. Having thus prepared the scalp, the affected parts are next covered with an ointment composed of chalk, silex, alum, oxide of iron, a small quantity of subcarbonate of potassa, some lime, and a little charcoal rubbed up with lard, but in proportions which are kept secret. This ointment is applied on alternate days for upwards of a month; whilst on the intermediate days a comb is passed gently over the parts to detach the loosened hairs with as little pain as possible. At the end of this time a powder, the same as that which was employed in forming the ointment, but without any charcoal, is sprinkled over the affected parts; and after using the comb on the following day, the former ointment is again resorted to; and by continuing this method the disease yields, and the skin again acquires its natural and healthy condition. We have had no experience of this method of treating this species of porrigo; but from its reputation in Paris we are of opinion that it merits the attention of British practitioners.

Many other local stimulants have been employed with various success; for example, ointments composed of powdered charcoal, peroxide of manganese, and oxygenated lard; cantharides ointment, and pommades made with white precipitate, or calomel, or bichloride of mercury. Different anodyne cataplasms also have been recommended, made chiefly with strong decoctions of conium *maculatum* or of the twigs of dulcamara; but at best these may be regarded simply as palliatives to allay local irritation. In obstinate cases, after removing the crusts, it has been found useful to touch the raw surfaces with a feather dipped in any of the mineral acids, and then a few minutes afterwards to bathe the parts repeatedly with cold water. The pain excited is great; consequently some degree of caution is requisite in applying these caustics to children of delicate habits.

When the eruption appears on the trunk of the body, the ordinary warm-bath is found to be beneficial, and still more so the sulphurous vapour-bath.

[Alkaline ointments and washes; weak solutions of chlorinated lime or chlorinated soda or of creasote may be employed; and in some cases, solutions of sulphate of zinc or of sulphate of copper or of nitrate of silver have been of great service. The citrine ointment, unmodified, or re-reduced, according to circumstances, has been advised by many. In the author's experience more good has been derived from the ointment of iodide of sulphur than from any other application. Cod-liver oil is likewise said to have been used with advantage; but it would be endless to enumerate all the topical applications that have been advised. (For a further detail see the author's *Practice of Medicine*, 2d edit. ii. 126.)]

In conclusion, it is necessary to recollect that in no cutaneous eruption is a change of measures more necessary than in this species of porrigo; the employment of any single remedy, however judicious, is not likely to be followed by success.

II. **Eczematous Porrigo.**—*Species* 4. *Porrigo furfurans; furfuraceous scall.*—This is the teigne *amiantacée* and teigne *furfuracée* of Alibert; the eczema *de cuir chevelu* of Biett, Rayer, and some other French writers: but as there can be only one opinion as to its pustular nature, it cannot be regarded as a variety of eczema, although it may be characterized as an eczematous porrigo. The eruption most commonly appears on the nape of the neck, at the margin of the hairy scalp, or on the temples. It commences with a crop of minute achores, the pus in which being unusually transparent has led them to be mistaken for vesicles. The discharge is moderate, and soon concretes, forming thin, laminated, exfoliating scales, accompanied with much itching and soreness when the disease, as is most commonly the case, is seated in the scalp and extends to the temples, ears, and neck. The discharge is also viscid, and exhales a nauseous odour; it adheres to the hairs; and on drying forms a powdery scurf, which the slightest friction separates; and when confined under these scales, it is absorbed, and the glands of the neck swell and become painful. This also occurs in old cases; whilst the inflammation extending to the bulbs of the hairs, these fall off and baldness appears.

This species of porrigo generally attacks adults, females rather than males, and always those of a lymphatic temperament. The eruptions with which it is most likely to be confounded are psoriasis, and lepra when the latter affects the scalp. We have seen it also assume the appearance of impetigo. The pustular origin of the disease, as it appears at irregular periods, enables us very readily to form a correct diagnosis; and independent of this, we observe no moisture nor ulceration, nor any diseased condition of the hair in either psoriasis or lepra; nor are these eruptions conta-

gious, whilst porrigo *furfurans* is undoubtedly communicable by contact.

Porrigo *furfurans* is usually treated solely by topical remedies; but we have never seen it yield without the employment of general means. We have found much benefit by prefacing a light alterative course, with one or two moderate bleedings, and a full evacuation of the alimentary canal by means of six or eight grains of calomel, followed by a brisk saline purgative. We then generally order ten grains of hydrargyrum cum creta to be taken daily at bed-time, and twenty minims of liquor potassæ three times a day, gradually increasing the dose until it reach to ninety or one hundred drops. The best vehicle is milk, which both covers the taste and sheaths the acrimony of the medicine in swallowing. We have occasionally carried the dose to the extent of one hundred and twenty minims without any inconvenience to the patient.

With respect to the local treatment, the first object is to free the scalp and the hairs from the scurf, which is easily accomplished by cutting the hair short, and using a solution of f.ʒiv of liquor potassæ, in f.ʒvss of bitter almond emulsion as a lotion. The same lotion, more largely diluted, may be applied, tepid, twice a day: it cleans the scalp better than soap and water, and prepares it for the application of a stimulant ointment, which should be kept on, and the surface at the same time preserved in a moist state by an oil-silk cap accurately fitted to the shape of the head. The nature of the ointment must depend upon the greater or less irritability of the affected surface. When the scalp is very tender and moist, the oxide of zinc ointment should be preferred; or an ointment prepared with two parts of finely powdered cocculus indicus and eight of lard. In a drier and less sensitive condition of the diseased parts, the strong lotion may be used daily, or one composed of ʒiij of recently prepared sulphuret of potassæ, ʒi of soft soap, ʒviij of lime water, and ʒij of rectified spirit; or with a lather formed with equal parts of soft soap and sulphur ointment in hot water. Instead of the unguentum oxidi zinci, either the unguentum hydrargyri nitratis, or unguentum hydrargyri nitrico-oxydi, or unguentum acidi nitrici of the Edinburgh Pharmacopœia may be now used; or, what in our opinion is preferable to all of these, a mixture of the common tar and sulphur ointments. By the employment of such means the disease usually yields, but as the inflammatory symptoms frequently recur, it is necessary, under such circumstances, to return to the use of the milder applications. All salted meats, pork, and fish should be forbidden during the existence of the eruption.

III. **Anomalous Porrigo.**—This division of porrigo contains chronic inflammatory affections, of a contagious nature, characterized by extremely minute circular groups of achores, which exude a fluid that concretes into thin, slightly adhesive crusts. In one of these species both the achores and the crusts are so minute as to be almost microscopic objects.

Species 5. *Porrigo scutulata; ring-worm of the scalp.* This is the most difficult to manage, and the most decidedly contagious of the whole genus. The pustules, or achores, are generally scated on the scalp, although occasionally they appear on the forehead and neck in distinct, somewhat distant, circular patches. When these are closely examined with a magnifying glass, they are found to consist of very minute whitish-yellow pustules, embedded as it were in the epidermis. These break and are succeeded by thin crusts, which are readily detached at first, but after a short time harden, and become adhesive as they accumulate. The first circular patch, after the pustules break, is in a few days surrounded by a circle of fresh pustules, which break and crust in their turn, and are surrounded by a new crop of pustules; and by these repetitions the areas of the patches extend, until the greater part of the scalp is covered by them. The pustules are generally preceded by erythematic patches, which itch: when carefully examined, M. Biett says that, like porrigo *favosa*, each pustule has a central depression, and is generally traversed by a hair; and when the crusts in which they terminate exfoliate, the surface remains red, shining, and inflamed. If the hair falls off, which generally occurs, the new hairs are dry, woolly, and so little adhesive that they may be detached with the smallest effort. The various patches display different periods of the eruption, and each is surrounded by an external circle of recent inflammatory pustules. The duration of the discase is very uncertain; but under every circumstance, even the most favourable, the prospect of cure is always a distant one. When the circles remain red, smooth, shining, dry, o scurfy, the disease is still in progress; but when the redness and exfoliation disappear together, and the hairs begin to cover the spots and assume their natural appearance and colour, it may be regarded on the decline.

With regard to the causes of this disease, it is said to originate spontaneously in weak, flabby children, badly nourished, and who are confined to close ill-ventilated apartments; but there is some reason for thinking that it is one of those evils which our oriental possessions has bestowed upon us, (for we think that it is imported from India,) and that its general propagation is due to its highly contagious character. Its introduction into a school is sufficient to fix it in the establishment for years, in spite of the greatest vigilance and attention on the part of the superintendents. It occasionally, but rarely, occurs in adults.

The circular form of the patches, their manner of extending, the minuteness of the achores, and their contagious nature, readily distinguish this species of eruption from all others. It may nevertheless be confounded with impetigo *figurata* when this appears on the hairy scalp; but there are distinctive characters sufficiently evident to separate the two: thus, the superficial, slightly prominent psydracious pustules of impetigo *figurata*, seated on a diffused red surface, differ essentially from the imbedded pustules of porrigo *scutulata*, surrounded by inflammation only at their base. Impetigo *figurata* also seldom appears exclusively upon the scalp, nor is it contagious.

If the spontaneous appearance of porrigo *scutulata* be true, it is evident that the tone and vigour of the constitution should be brought up where that is deficient; thence gentle alteratives, namely, minute doses of hydrargyrum cum creta, with

decoction of bark, or the solution of hydriodate of iron or other chalybeate preparations, are indicated when the disease appears in cachectic habits. When, on the contrary, it is communicated by contagion to stout and healthy children, no general treatment is required. In both, however, some attention to diet and regimen is necessary; all crude aliments, raw vegetables, and sweetmeats, or whatever is likely to prove accscent, should be avoided; and the surface of the body, particularly the lower extremities, must be kept warm, so as to maintain the balance of the circulation and keep up the insensible perspiration. In a word, every thing should be done to improve the general health if that is defective, and to preserve it if it do not require improvement.

The local treatment must be varied according to circumstances. In the early stage of the disease, when the patches are inflamed and irritable, soothing applications are indicated; for example, sponging with warm water, lime-water, or the application of emollient poultices, after shaving the head, which should be done at least once a-week; but we have seen more advantage derived from the simple application of cold or iced water to the patches, at this time, than from any warm or tepid application. A light linen cap should be worn, and changed daily, and every pains taken to preserve cleanliness, and to prevent scratching or any mechanical irritation of the scalp. As the inflammatory state diminishes, and a dry, harsh state of the patches ensues, provided no fresh circles of pustules rise, and produce tender, inflamed areolæ, stimulant applications are indicated. During the irritative stage, Alibert recommends a cataplasm of hemlock, which we have tried, as well as cataplasms of henbane and belladonna, without observing any decided benefit to follow their employment. The belladonna causes dilatation of the pupils, blindness, vertigo, and other nervous symptoms, and therefore it requires to be used with caution, especially in young subjects. If ointments are desirable at this period, those prepared with cocculus indicus, calomel, white precipitate, oxide of zinc, the acetates of lead, or with opium or tobacco, are chiefly recommended. Decoctions of poppy heads or of tobacco have also proved beneficial; but the latter requires more caution than the belladonna poultice. We have seen it cause sickness, vertigo, and the most alarming degree of collapse.

When the inflammatory state is absent, every stimulant that can be externally applied has been used in this complaint. Ointments, formed of metallic oxides and salts, namely, unguentum hydrargyri nitratis, unguentum hydrargyri nitrico-oxydi, and Banyer's ointment* containing calomel; sulphur ointments; the tar ointment, or one resembling it, made with petroleum instead of tar; ointments containing white hellebore, sabadilla, mustard, staves-acre, black pepper, capsicum, galls, rue, and similar vegetable excitants have been employed, and each in some cases has proved successful; nevertheless all have occasionally failed. In India, where the disease prevails, an ointment composed of ʒi. of powdered galls, ℈i. of sulphate of copper, and ʒi. of simple cerate is said to prove successful. In this country the last application in vogue is creasote;† we have witnessed its success, but experience has yet to determine how far it can be depended upon. In very dry, rigid, inert states of the patches, the nitrate of silver, the strong mineral acid, the pure alkalies, and other caustics have been applied, with the view of destroying the morbid cuticle and setting up a new action in the part. In some cases we have seen this practice succeed: in many instances, however, like other applications, it is useless. Although none of these external remedies when singly relied upon is permanently successful, yet all of them, when alternately employed or variously combined, are productive of benefit. As far as our own experience has enabled us to form a judgment on this subject, we are of opinion that more benefit is derived from the use of the depilatory method mentioned under the head of porrigo *favosa* than from any other mode of management. It is undoubted that, whether the disease be seated in the bulbs of the hairs, or whether these become mere irritating bodies, the removal of the hairs is an important step in forwarding the cure. When these are once removed, the application of any stimulant ointment, exciting a new action in the diseased spots, aids the cicatrization of the pustules, and the formation of a healthy cuticle. The best and most certain evidence of the cure being completed is the growth of healthy, good coloured hair on the spots which were previously the sites of the pustules.

Species 6. *Porrigo decalvans; bald scall.*—This species, which is easily recognised from all the other species, and indeed from every other cutaneous disease, is the area *alopecia* of Celsus, the alopecia *areata* of Sauvages, and the trichosis area of Good. (See Alopecia.) It is characterised by patches of baldness in different parts of the head, generally of a circular form, with the naked part of the scalp smooth, shining, and white. No crusts form on these patches, nor can any achores be detected even when a good eye is aided with the most powerful glasses. Sometimes the patches enlarge, and run into one another so as to produce baldness of the greater part of the scalp.

It is extremely difficult to trace the cause of this curious disease. It seems to be some morbid condidition of the secreting follicles of the hair, for

* Banyer's ointment consists of lb.ss of litharge, 2 oz. of burnt alum, 1 oz.ss of calomel, lb.ss of Venice turpentine and 2 lbs. of lard, well rubbed together. It is too acrid for all cases, consequently it requires dilution with more lard.

† As this substance has very lately been introduced to the notice of the profession in this country, it may be useful to give here some account of it. Creasote is a colourless transparent liquid; sometimes, however, it is of a pale yellow colour. Its specific gravity is 1·037. It remains fluid at —17° and boils at 397° Fahrenheit. It impresses a hot taste on the palate, followed by sweetness; its odour resembles that of Westphalia ham. The antiseptic properties of pyroligneous acid are ascribed to Creasote. It is soluble in eighty parts of water, and in every proportion in alcohol, ether, and naphtha. It combines with acids and alkalies, forming compounds soluble in water. It coagulates powerfully albumen. Finally, it is a compound of carbon, hydrogen, and oxygen.

Such are the physical and chemical properties of this substance. It operates as an energetic excitant to the animal system, and proves poisonous to fish when they are introduced into aqueous solutions of it. As a therapeutical agent, it rapidly exhausts nervous energy, and therefore displays a narcotic as well as an excitant influence. It has been administered internally in rheumatism, hysteria, and several other diseases, and it has certainly been found useful as a topical remedy in ulcers and several cutaneous diseases, but hitherto its administration has been directed rather by empirical than scientific principles.

there are no achores apparent, nor any disease of the cutis, unless we can regard the pale exsanguine aspect of the bald spot to be the result of some contracted state of the capillaries. There is a slight degree of itching, indicating nervous excitement on the patches; but this is not always present. Dr. Bateman (Synopsis, p. 248) hints that the disease is contagious: we have not seen any cases in which it could be traced to communication. It occurs most frequently in children of ten or twelve years of age; but it is also occasionally observed in adults.

With respect to the treatment of this species of porrigo, we have seldom failed to cure it by shaving to the extent of an inch round the bald patches, and brushing them, at least twice a day, with rectified oil of turpentine, diluted with two parts of alcohol. As the new hair begins to appear on the bald parts, it should be regularly shaved off as long as it is softer and of a lighter colour than the healthy hair of the individual, the re-appearance of which is the proof of the termination of the disease. No internal medicines are indicated.

A. T. Thomson.

PREGNANCY AND DELIVERY, SIGNS OF.—Few questions in legal medicine, whether considered in a merely professional point of view, or in reference to their relations with criminal or civil law, impose on the medical examiner a more delicate duty, or a more trying responsibility, than the determination of the existence or absence of pregnancy; placed before him, as the question generally is, under circumstances by which all its natural difficulties are increased an hundred fold. It usually happens in such cases that he cannot rely on a single statement made by the individual who may be the subject of examination; but, on the contrary, he must be prepared for every species of falsehood and misrepresentation. And yet on the correctness of his opinion frequently depend the claim to fair fame, virtue, and honour;—the succession to property, and the rights of legitimacy;—the judicious treatment of disease;—and, in criminal cases, the preservation or destruction of the unborn innocent.

The instances which present themselves are unfortunately but too frequent, in which the unmarried female, either yielding to the influence of passion, or made the reluctant victim of the unprincipled seducer, and becoming pregnant, an investigation as to her real state is sought for, in the hope of inducing marriage, or perhaps for the purpose of influencing a jury in the assessment of damages.

An attempt may be made to *conceal* pregnancy by the unmarried, or even by the married under certain circumstances; as in the case of a wife's separation from her husband or his casual absence, in order to avoid disgrace in society, or to enable her with impunity to destroy her offspring. On the other hand, pregnancy may be *feigned* in order to gratify the wishes of a husband or relatives, to extort money, to compel marriage, to deprive the lawful heir of his just rights of succession, or to delay the execution of the sentence of death.

By the law of this country, a woman condemned to death may plead pregnancy in bar of execution, and medical men are appointed to determine the question whether the culprit is really with child or not; and if she is, whether she be *quick with child*, for pregnancy alone will not save her. This rule, we may observe in passing, is one of the most monstrous and barbarous features of our penal code.* Infinitely superior both in morals and in mercy is the law of France, which ordains that if a woman be pregnant at all, she shall not be executed until after her delivery; and formerly the privilege allowed under such circumstances was even greater: in 1795 a law was passed which ordained that no woman accused of a capital crime should be *brought to trial* until it was properly ascertained *that she was not pregnant*, (see observations on *Quickening* in the present article,) and in conformity with this, several decisions were reversed where it appeared that the female had not been properly examined; and in more than one instance the sentence of death was annulled, because after the trial it was discovered that the woman was pregnant at the time of being put upon her trial. (*Fodéré*, Méd. Lég. vol. i. p. 428, et seq.)

Connected with such investigations, some very melancholy mistakes have occurred, by which the lives of unborn infants have been sacrificed. Riolan relates the history of a woman named Genevieve Supplice, who, after being hanged for robbery, was publicly dissected by him at the school of medicine, and was found pregnant of a child of five months, contrary to the opinion of the surgeons and midwives who had examined her. (Anthropog. lib. 6, ch. 2.) Mauriceau also mentions having seen at Paris, in 1666, a miserable example of this kind in a woman who was hanged and afterwards publicly dissected: she was found to be pregnant four months, notwithstanding the report of the persons who had visited and examined her by order of the judge before her execution, and pronounced that she was not pregnant, being deceived by the fact of her continuing to menstruate. This matter caused a great sensation of disgust and horror, and was reported to the king and his court, and in consequence a severe censure was passed on the persons who, by their ignorance, had caused the untimely execution of the unfortunate woman, with whom had perished also her infant, innocent of its mother's crime. (Maladies des femmes grosses, tom. i. p. 71-2.)

A proceeding may also take place at common law, "where a widow is suspected to feign herself with child in order to produce a supposititious heir to the estate, and defraud the lawful heir. In such case the heir presumptive may have a writ *de ventre inspiciendo*, to examine if she be with child or not, and if she be, to keep her under proper restraint until she is delivered. But if the widow be, upon due examination, found not pregnant, the presumptive heir shall be admitted to the inheritance, though liable to lose it again on the

* Pregnant women have always been objects of much regard and reverence. The Roman laws allowed them the same privilege as those of France. The ancients even spared the life of the murderer who took refuge under the roof of a woman with child. The kings of Persia used to present two pieces of gold to each pregnant woman. The Jews, who observed so rigorously the Mosaic law, allowed them the use of forbidden meats, lest the child might suffer from their longings.

birth of a child within forty weeks from the death of the husband." (*Blackstone*, vol. iv. p. 394-5.)

A celebrated case of this kind, which attracted great attention, occurred in the family of Sir Francis Willoughby, who died, seised of a large inheritance. He left five daughters, (one of whom was married to Percival Willoughby,) but not any son. His widow at the time of his death stated that she was with child by him. This declaration was evidently one of great moment to the daughters, since if a son should be born, all the five sisters would thereby lose the inheritance descended to them. Percival Willoughby prayed for a writ *de ventre inspiciendo*, to have the widow examined, and the sheriff of London was accordingly directed to have her examined. He returned that she was twenty weeks gone with child, and that within twenty weeks *fuit paritura*. "Whereupon another writ issued out of the Common Pleas, commanding the sheriff safely to keep her in such an house, and that the door should be well guarded; and that every day he should cause her to be viewed by some of the women named in the writ, (wherein ten were named,) and when she should be delivered, that some of them should be with her to view her birth, whether it be male or female, to the intent there should not be any falsity. And upon this writ the sheriff returned, that accordingly he had caused her to be so kept, and that on such a day she was delivered of a daughter."*

There is another case where the court has interfered on proof of the existence of pregnancy being brought before it, and that is, where a female in this situation is imprisoned. Thus in the case of Elizabeth Slymbridge, (Croke's James, p. 358,) "upon suggestion that she had been imprisoned for divers weeks and was with child, and would be in danger of death if she should not be enlarged," Sir Edward Coke, the Chief Justice, admitted her to bail to prevent the peril of death to her and her infant, and in giving his opinion he quotes a similar case which happened in the 40th of Edward III. The editor remarks that these cases are cited as extraordinary instances. The last case is mentioned in Coke upon Littleton, 289 *a*.—The record states: "Quia eadem Elena pregnans fuit, et in periculo mortis, ipsa dimittitur per manucaptionem ad habendum corpus," &c.

When proceeding to an investigation of this kind, we must recollect that the signs or proofs of pregnancy are to be collected from various and very different sources, and, moreover, that of some of them we can have no evidence except from the report made to us, while of others we can judge by the changes existing before us, and cognizable by our senses. The following are the chief of these signs:—

1. Certain affections of the constitution induced by pregnancy, which are the result of the new action which has commenced in the uterus; such as suppression of the menses, generally increased irritability of the nervous system, evinced in capriciousness of temper, or perhaps in the production of erratic pains, as in the face and teeth, greater activity in the circulating system, and especially in the exhalents, giving rise to œdema and other forms of dropsical effusions; alterations in the countenance from absorption of the fat, &c.

2. In consequence of the irritation induced in the uterus, there are a train of sympathies excited in other organs, affecting either their physical constitution or their peculiar functions: such, for instance, are the changes produced in the breasts by which their size is increased, with tingling pains, the areola formed, and milk secreted; the stomach is irritable; vomiting ensues; the appetite becomes variable and capricious, and sometimes the salivary apparatus participates so decidedly in the irritation that complete salivation takes place.

3. The altered condition of the uterus itself, which, increasing in size, ceases to be a pelvic organ, and rises into the abdomen, which in consequence becomes enlarged and prominent, and a corresponding change is effected in the state of the umbilicus; while at the same time certain alterations take place in the os and cervix uteri, affecting their form, texture, &c. which we can recognize by touch.

4. The contents of the uterus so enlarged; the presence of a fœtus therein, and its motions, which we endeavour to ascertain by manual examination, both *externally* through the abdominal parietes, and *internally* per vaginam; and also by the adoption of auscultation to discover the pulsations of the fœtal heart and the placentary sound.

5. Certain organized substances may, under suspicious circumstances, be discharged from the uterus, by a proper examination of which we may be enabled to determine whether they are the product of conception, and of course proofs of pregnancy.

6. After death we may be called on to make an investigation for a like purpose, and, by examination of the uterus and its appendages, to determine the question of actual pregnancy, or of previous impregnation. We shall notice the principal of these signs in detail.

Suppression of the Menses.—This is one of the symptoms of pregnancy our investigation of which must almost always be encumbered with this difficulty,—that our knowledge must be derived from the statement of the female herself, nor can we have in general any certain means of disproving or confirming her assertion. It is moreover a circumstance which, notwithstanding its general subjection to a fixed law, has been fully proved by experience to be liable to very many exceptions and deviations.

We are indeed quite justified in adopting as a general rule that in healthy women, whose menstruation has been established and continued regular, and who are not nursing, conception is followed by a suppression of the menstrual discharge at the next return of its period; but then this suppression may not so occur, and on the other hand it may happen from a variety of other causes altogether unconnected with pregnancy: for these reasons we ought, whenever we come to consider this sign, to weigh very fully all the possible circumstances of the individual case before us, and view it in relation to the various exceptions which

* Croke's Elizabeth, p. 566. See also in the matter of Martha Browne *exparte* Wallop in Brown's Chancery Cases, vol. iv. p. 90: and *exparte* Aiscough. Peere Williams' Reports, vol. ii. p. 591.

experience has from time to time shown to exist. Thus we must recollect that cases have occurred in which conception took place previous to menstruation. One instance of this happened under our own observation, and a very remarkable one is mentioned by Morgagni in these words: "I was acquainted with a maiden of a noble family who married before menstruation took place, though the menses had been expected for some years; nevertheless she became exceedingly fruitful. We were the less surprised at this circumstance because the same thing had happened to her mother."* Frank had a patient who gave birth to three children without ever having menstruated or had lochial discharge, and he saw three others who never had the catamenia, but were not deficient in lochia after delivery. (De Morb. Hom. Curand. art. *Amenorrhœa.*) A woman, 55 years of age, very lately resided in Cornwall, who had borne several children and always enjoyed good health, but had never menstruated or had vicarious discharge of any kind.† Capuron quotes several cases of fecundity without menstruation, (Méd. Lég. relat. à l'accouchement, &c. p. 96–7,) and Foderé assures us of the fact. ("J'ai eu occasion de m'assurer completement de ce fait." tom. i. p. 395.)

Some women are very irregular in the returns of their menstrual periods, having them prolonged much beyond the usual interval. The writer lately attended an unmarried woman of 40 affected with polypus uteri, who assured him that the returns of the catamenial discharge with her had been frequently deferred for more than six months without any accompanying circumstances of ill health: instances of habitual suppression for shorter periods are frequently met with. Zacchias mentions that he attended a patient who used to menstruate regularly, but who never conceived until the discharge had been suppressed for three or four months previously. A case somewhat similar is related by Mauriceau, (Observation 556, tom. ii. p. 461,) who very justly remarks that such cases not unfrequently give rise to the supposition of protracted gestation.

At the period which is usually denominated *the change of life*, it is very usual to have the menses suppressed for two or three months and then return profusely, giving rise to the idea of pregnancy and abortion, both suppositions being equally unfounded.

On the other hand cases occasionally occur in which women have conceived after menstruation had apparently ceased.

In married women, and others who have been incurring the risk of pregnancy, suppression may arise from a variety of causes altogether independent of conception, such as different forms of disease, exposure to cold and hardship, mental emotions, particularly that of fear, the effects of which latter we have had an opportunity of observing in very numerous instances, in some of our prisons, where young women constantly apply to the physician in consequence of their menses being suppressed, which they very often, and apparently with great reason, ascribe to the alarm and terror which they suffered when arrested and carried to prison.

A woman may conceive while she is nursing, without any previous return of the catamenia, which, however, very usually happens in such cases, as observed by Denman.

Here, then, we have a variety of cases in which the absence of the menstrual discharge could not be made a means of diagnosis, or, if assumed as affirmative of pregnancy, would lead us into absolute error.

It now remains to view the matter in another light, and inquire, how far the presence of the catamenia can be considered as evidence that the woman is not with child.

We have met with several instances of menstruation occurring *once* after conception, and at this moment we are in attendance on two ladies to both of whom it happened; and one of them who has borne three children and is now a fourth time pregnant, assured us that she always knew when she had become with child by the unusual profuseness of the next period. This is distinctly taken notice of by Johnson, who says, "some have the menstrua copiously at the first period." (System of Midwifery, p. 100.) A diminution in the quantity under similar circumstances has, however, been more frequently observed. "I have seen," says Desormeaux, "some cases in which the appearance of the menses in small quantity and at an unusual time, was almost a certain sign of conception." (Dict. de Méd. vol. x. p. 394.) A similar remark is made by Pazos, Stein, and Gardien. (Traité des Accouchemens, vol. i. p. 489.) An interesting case, which confirms this remark, is detailed by Dr. Dewees. (Compendium of Midwifery, p. 165.) A gentleman, who had been obliged to absent himself from his family for many months, returned secretly and spent one night at home with his wife, in consequence of which she conceived, as the event proved, although the regular return of her catamenia a week afterwards in their usual quantity, had led her to expect that she had escaped with impunity.

Again, there are individuals who menstruate with regularity *for more than one period* after conception. "It is well known," says Burton, (New System of Midwifery, p. 285,) "by experience, that the menstrual discharge sometimes continues in its usual regularity for two or three months after conception without any dangerous consequences." Instances of this are not at all unfrequent, and are quoted by all who have written at large upon this subject.‡ It has been asserted as an objection, that these discharges are not truly menstruation; but the discussion

‡ *Capuron*, Méd. Légale, p. 63. *Belloc*, Quest. Méd. Lég. p. 62. *Mauriceau*, vol. i. p. 72, 155. *Dewees*, Compendium, p. 93, et seq. *Desormeaux*, Dict. de Méd. vol, x. p. 394. *Gardien*, vol. i. p. 489. *Gooch*, Diseases of Females, pp. 202-3. *Van Swieten*, Commentaries, vol. xiii. pp. 379, 468. *Bech*, Principles of Med. Jurisp. p. 76. Van Swieten supposes such discharges do not proceed from the same source as the regular menses, "but from the vessels distributed about the vagina and the external surface of the neck of the womb." A similar opinion is maintained by Hoffman, Med. Ration. et. Syst. tom. iv. part 2 cap. 623, and by Frank.

of that question does not concern us here. We have only to consider whether there does not frequently, during pregnancy, take place a coloured discharge from the vagina, so closely resembling menstruation in its periods, quantity, and duration, that neither the woman herself nor the medical inquirer shall be able to detect any difference between them; and of this we must declare with Dewees and Gooch, "there can be no doubt."

In still more rare instances, of which we have ourselves never met one, but which are recorded by writers of credit, women have continued to have these discharges through nearly the whole period of pregnancy. (*Foderé*, vol. i. p. 437.) Dewees mentions an instance in which this happened to both mother and daughter, (*Dewees*, Comp. Mid. p. 96,) who were in the habit of menstruating up to the seventh month. "On a vu," says Gardien, "chez des femmes jeunes et pléthoriques l'évacuation menstruelle continuer pendant les trois ou quatre premiers mois, quelquefois même pendant tout le cours de la grossesse." (Traité des Accouchemens, tom. i. p. 489).

The last, and perhaps most remarkable exceptions to the general rule, to which it appears necessary to allude, are those very singular cases in which menstruation has either appeared for the first time after conception, or in which it continued only during pregnancy. Perfect's eightieth case (Cases in Midwifery, vol. ii. p. 71) affords a very satisfactory instance of the former; and Daventer, Dewees, and Baudeloque,* furnish us with examples of women whose habit it was to menstruate *only* during pregnancy, and who did so through the whole period of that condition, though never at any other time.

There is a source of deception against which we can hardly guard, and which we know to have been resorted to by a young woman in one instance. She apprehended that she was pregnant, but deceived those about her by staining her linen at the usual periods of menstruation: this completely lulled the suspicion of her friends for two months, but in the third a circumstance was discovered which proved that she had incurred the risk of pregnancy, and the writer was requested to see her. On looking at her breasts, the areolæ were so distinct, and exhibited their proper characters so perfectly, that he felt persuaded she was pregnant; and perceiving that her breasts were marked with the silvery lines observable on parts formerly much distended, he told her his opinion that she was then with child, and moreover that she certainly had been so before. This completely took her by surprise, and she acknowledged that she had given birth to a child about two years before, and had suffered much from the distension of her breasts during pregnancy. The event also proved that we were correct in supposing her pregnant then, as she was afterwards in proper time delivered of a full-grown child.

Belloc, p. 65, takes notice of this kind of imposition, which he informs us was attempted on himself by a girl three months advanced. "Il faut alors exiger que les parties soient lavées avec de l'eau tiède; si le sang ne reparait pas, le cas est suspect." (*Capuron*, p. 81. See also *Beck*, p. 76, and *Mahon*, Méd. Légale, vol. i. p. 153. *Foderé*, tom. i. p. 438.)

We should not forget that there are cases occasionally met with, in which suspicions arise in connection with a non-appearance of the menses, the elimination of the discharge being prevented by some adventitious structure or imperforate state of some of the natural parts, especially of the hymen. In such a case the secretion takes place, but being prevented from leaving the body, accumulates within, distending the vagina and the uterus, and so giving rise to several of the sympathies usually accompanying pregnancy. We had very lately an instance of this under our care in a girl of 17, who between the age of 15 and 16 began to exhibit the signs of puberty. When we saw her, suspicions had been excited of her being pregnant. The abdomen was enlarged, and the uterus could be felt as high as the umbilicus, the breasts were painful, and she had occasional vomiting, and pain in the back and along the thighs. Complete inability to pass water was the cause of our being requested to see her, and on hearing the above detail of symptoms, we confess we had our suspicions too, but did not express them: on attempting to pass the catheter we encountered a soft elastic tumour protruding from the external parts, displacing the urethra, and concealing its orifice. This rendered a closer examination necessary, which detected the hymen attached completely all around, and distended by fluid from within: having relieved the bladder, we punctured the opposing membrane and gave exit to about three pints of a dark chocolate-coloured fluid, without smell and uncoagulated.

Frank (Epitome de Morbis Hominum Curandis. Art. *Amenorrhœa*,) mentions two such cases, in one of which the abdomen was as much enlarged as at the sixth month of pregnancy, and the girl herself thought that she felt a foreign body in the uterus, which, however, was found to contain five pounds of a dark and thick blood, without any offensive odour: in the other case the girl was believed to be with child, and in consequence suffered temporary loss of reputation, but the hymen was found imperforate, and, when punctured, gave passage to several pints of blood.

Madame Boivin (Mémoire sur les Hémorrhagies internes de l'Utérus, p. 73,) has collected the details of ten such cases, among which are two much in point. In one from Denman the girl was submitted to examination from a belief that she was with child: the uterus was as high as the navel, and contained no less than four pounds of blood of the colour and consistence of tar. (Introduction to Midwifery, p. 87. 5th ed.) The other case occurred to Dr. Macauly, in a young woman of 19, whom he supposed to be not only pregnant, but in labour, as she had pains, and he felt what he thought was "the membranes with the water pushing low down." (Smellie's Cases in Midwifery, vol. ii. p. 15.) On puncturing the hymen there came away two quarts of thick black blood. In a case of obstruction related by Dr. Dewees, he mentions that he was fully impressed with the belief that pregnancy existed, as he could distinctly feel the enlarged uterus, and even thought

* *Daventer*, Novum Lumen Art. Obst. cap. xv. p. 54. *Dewees*, Comp. Mid. p. 97. *Baudelocque*, Art. d'Accouchement, vol. i. p. 197-8. Ed. 1822.

he felt the motion of a fœtus. (Essays on several subjects, &c. p. 337.)

Such exceptions should always be taken into account, to guard us against error, but on the other hand absence of the menstrual discharge in an otherwise healthy woman is always a circumstance of great importance, concerning which the remark of Belloc is deserving of great attention. "When a female," says he, "experiences suppression along with other symptoms of pregnancy, we may consider her situation as yet uncertain, because these signs are common to amenorrhœa and pregnancy. But if towards the third month, while the suppression continues, she recovers her health, and if her appetite and colour return, we need no better proof of pregnancy. Under other circumstances her health would remain impaired, and even become worse." (Cours de Méd. Légale, p. 60.)

Nausea and vomiting. — In general, when pregnancy has occurred, the stomach becomes irritable, in consequence of which the woman is distressed with nausea and vomiting, especially in the early part of the day: in some this commences almost immediately after conception. We had once a lady under our care, in whom there was reason to believe it began the day after marriage, and the date of her labour corresponded to such a belief: most frequently it occurs for the first time between two and three weeks after conception, in others not for as many months, and in some not at all: of this we have now seen several instances.

On the other hand, irritability of the stomach may occur from a variety of causes totally independent of pregnancy, and connected with disease or disordered function, such as suppressed menstruation, so that we must be slow to draw an inference merely from the presence of such a symptom: at the same time a proper degree of inquiry will generally enable us to distinguish between the two kinds. The vomiting of pregnancy is not accompanied by any other symptom of ill health; on the contrary, the patient feels perhaps as well as ever in other respects, and may even take her meals with as much appetite and relish as at other times, but while doing so, or immediately after, she feels suddenly sick, and has hardly time to retire when she rejects the whole contents of the stomach, and presently feels quite well again: in some instances, however, the woman is distressed by a perpetual nausea, and in a few rare cases vomiting has been so excessive as to endanger the life of the woman from inanition. (See Mem. Lond. Med. Soc. vol. ii. p. 125. Med. Chir. Trans. vol. iii. p. 139. Ashwell on Parturition, p. 194.)

Salivation.—By an extension of the sympathetic irritation which in the stomach causes nausea and vomiting, the salivary apparatus is in some persons excited to such a degree as to produce complete and copious salivation. This fact was expressly noticed by Hippocrates as one among the symptoms of pregnancy, (the passage is quoted by Van Swieten, vol. xiii. p. 371,) and has been observed by many others since. (See Gardien, vol. ii. p. 32. Burns, p. 237.) Dr. Dewees records a well-marked instance of the kind, (Compendium of Midwifery, p. 115,) and the writer of this article was consulted about another in which it occurred profusely in two successive pregnancies, but ceased immediately on delivery.

Affections of the Mammæ.—When conception has taken place, and the menses have been suppressed for one or two periods, the woman generally becomes sensible of an alteration in the state of the breasts, in which she feels an uneasy sensation of throbbing, or of stretching fulness accompanied by tingling pains felt about the centre of them and in the nipple. The breasts themselves grow sensibly larger and more firm; a circle around the nipple becomes altered in colour and in structure, constituting the areola; and as gestation advances, milk is secreted. But there is considerable variety in the period of gestation at which these changes may occur, as well as in the degree of their development; for while in some instances they may be recognised very soon after conception, in others they are hardly perceptible until gestation is far advanced, or even drawing towards its termination. In general, however, we may expect to find these sympathies (except the secretion of milk) established when two months of pregnancy have been completed; but any opinion deduced from their existence must be modified by several considerations. We must recollect that these changes of form and size may be the result of causes unconnected with conception. In many women the breasts enlarge merely in consequence of marriage and the habits thence arising; in others it may happen from the person becoming fat; it may be caused by accidental suppression of the menses, or their retention by an imperforate hymen, (see cases noticed under the preceding section,) or by any cause capable of distending the uterus. The enlargement from pregnancy may, however, in general be distinguished from that produced merely by fat, by the greater firmness of the breast, which also feels knotty and uneven when pressed by the hand. With some women of an irritable habit, swelling and pain of the breasts accompany each return of the catamenia, especially if they are the subjects of dysmenorrhœa; but under such circumstances the tension and uneasiness subside in two or three days, whereas that caused by pregnancy continues to increase, except when the ovum happens to be blighted, in which case the breasts become flaccid, and lose the characters which they had previously assumed. On the other hand it not unfrequently happens that in women of weakly and delicate constitution very little change can be observed in the breasts till pregnancy is far advanced. Gardien (Traité des Accouchemens, tom. i. p. 490) asserts that the swelling of the breasts is not observable in women who menstruate during the early months of pregnancy; and Mahon (Médecine Légale, tom. i. p. 151) makes the same observation. It should also be recollected that such a condition of fulness of the breasts may be natural to the individual, or it may take place at the turn of life, when the menses becoming naturally suppressed, the person grows at the same time fatter, and the breasts under such circumstances become full, and are not unfrequently painful,—which circumstances concurring are often improperly considered in the light of cause and effect, and irritability of the stomach being at the same time experienced, the woman believes herself preg-

nant. There is, however, one of those changes which, if carefully observed, is of the utmost value as an evidence of pregnancy, which, according to our experience, can alone produce it,—we allude to the altered condition of the areola.

The Areola. — The alteration which takes place in that part of the breast which immediately surrounds the nipple, and is called the areola, appears to us not to have received that degree of notice which its importance merits, as being one of the most certain external indications of pregnancy, arising from the operation of sympathy. On this, however, as on almost all other points connected with this investigation, a very marked difference of opinion exists; for while some suppose, with Denman, that the alteration in the areola "may be produced by any cause capable of giving to the breasts a state resembling that which they are in at the time of pregnancy," many others of equal authority maintain the opinion of Smellie and William Hunter, who regarded it as the result of pregnancy only: an opinion in which we entirely concur, and think we shall be able to show that much of the discrepancy of opinion on this subject has arisen from want of sufficient care in observing and accuracy in describing the essential characters of the true areola.

Most of those who have noticed this change appear, from their observations on it, to have attended to one only of its characters,—namely, its colour, which is, in our opinion, the one of all others most liable to uncertainty. We should here, perhaps, except the description by Rœderer, which is by far the most accurate we have met with:—"Menstruorum suppressionem mammarum tumor insequitur; quocirca mammæ crescunt, replentur, dolent interdum, indurescunt: venæ earum cœruleo colore conspicuæ redduntur, *crassescit papilla, inflata videtur, color ejusdem fit obscurior, simili colore distinguitur discus ambiens qui in latitudinem majorem expanditur, parvisque eminentiis, quasi totidem papillulis, tegitur.*" (Elem. Artis Obstet. pp. 46, 47.)

The several circumstances here enumerated at least ought in all cases to form distinct subjects of consideration, when we propose to avail ourselves of the condition of this part as an indication of the existence or absence of pregnancy. One other we shall add as equally constant, which is a soft and moist state of the integument, which, together with its altered colour, gives us the idea of a part in which there is going forward a greater degree of vital action than is in operation around it; and we not unfrequently find that the little glandular follicles are bedewed with a secretion sufficient to damp and colour the woman's inner dress. We must recollect also that these changes do not take place immediately after conception, but occur in different persons after uncertain intervals: we must therefore consider, in the first place, the period of pregnancy at which we may expect to gain any useful information from the condition of the areola.

We cannot speak very positively as to what may be the earliest period at which this change can be observed, but we have certainly been satisfied of its existence at the end of the second month, at which period the change of colour is by no means the most distinct character to be observed, but the turgescence of the nipple and the development of the little glandular follicles are the objects which should principally engage our attention; the colour at this period being in general little more than a deeper shade of rose or flesh colour slightly tinged with a yellowish or brownish hue. During the progress of the next two months the changes in the areola are in general perfected or nearly so, and it then presents the following characters: a circle around the nipple, whose colour varies in intensity according to the peculiar complexion of the individual, being generally much darker in persons with black hair, dark eyes, and sallow skins, than in those of fair hair, light-coloured eyes, and delicate complexions. The extent of this circle varies from a diameter of an inch to an inch and a half, and increases in some as pregnancy advances, as does also the depth of colour.*

In the centre of this circle the nipple is observed partaking of the altered colour of the part, and appearing turgid (Crassescit papilla, inflata videtur, *Rœderer,*) and prominent; and the part of the areola more immediately around the base of the nipple has its surface rendered unequal by the prominence of the glandular follicles, which, varying in number from twelve to twenty, project from the sixteenth to the eighth of an inch;† and, lastly, the integument covering the part is observed to be softer and more moist than that which surrounds it, and the breasts themselves are at the same time observed to be full and firm, at least more so than was natural to the person previously. Such we believe to be the essential characters of the true areola, the result of pregnancy, and that, when found possessing these distinctive marks, it ought to be looked on as the result of that condition alone, no other cause being capable of producing it.

But we cannot stop here and rest satisfied with the knowledge of the distinctly affirmative part of the question only, without also looking to certain circumstances which will most materially modify the certainty of our conclusions.

In the first place, then, pregnancy may exist, and the areola remain deficient in at least one of its usually essential characters, and that, the one too generally supposed to be its most important distinctive mark,—namely, the colour. Within the last few months the writer saw two well-marked instances of this; one in a lady of very fair skin, blue eyes, and light hair; the other in a lady of fair skin, but with black hair and very dark-brown eyes: in both, the colour of the areola was so slight as hardly to differ from that of the surrounding skin, and certainly was less distinct than we have frequently seen it in the virgin, but all the other changes which we have enumerated were well developed in both.

Again, we must recollect that a woman may be presented to us for an opinion, who having perhaps very recently miscarried, her breasts may exhibit all the true characters of the areola, com-

* We lately saw the areolæ on the breasts of a young woman, of very dark complexion, at the time of labour; they were of a very deep shade, and exceeded three inches in diameter. In negro women the areolæ is almost jet black.

† For a very full account of the structure of this part of the breast, see Meckel's Anatomy, vol. iii. p. 652.

bined with several other circumstances really indicating a state of pregnancy; but if we do not use great caution in giving our opinion, it will in such a case appear falsified by the event, although really correct. In nurses, also, the characters of the areola are kept up and continue in a state of considerable perfection.

Now, as to the colour alone, we may adopt this belief—that where we find it of a deep and dark brownish shade, forming a circle round the nipple, even though unaccompanied with the other changes natural to the part, it affords very strong presumptive evidence of a former state of pregnancy; but when so accompanied, it is a mark of great value, and in our experience has never yet deceived us: and we certainly never saw any other condition of the part produced by disease which could possibly be mistaken for it. At the same time it should be observed that the areola does not always, in pregnant women, present all the characters we have described as belonging to it. We have seen it at the time of labour presenting the dark circle alone without the prominence of the glandular follicles, but we never saw an instance of their development, as already described, without the concurrence of pregnancy: their absence, therefore, ought not to decide our opinion against the existence of that condition, though their presence would be with us a very convincing proof of previous conception: we should also be cautious in being influenced by the condition of this part, before the period at which its characters are in general developed and perfected, as already described.

A case which occurred recently, while the writer was lecturing on this subject, afforded a very satisfactory illustration of the value to be attached to this evidence of pregnancy. A young woman came a considerable distance from the country to be admitted into Sir P. Dunn's Hospital, the medical men in the country not having succeeded in affording her relief or restoring her health. A very prominent symptom of complaint was amenorrhœa of four months' duration, accompanied by uterine pain, want of appetite, &c. A very intelligent pupil suggested to the writer, after lecture, that he thought we must be mistaken in our account of the subject, as there was then in the house an unmarried patient, labouring only under amenorrhœa, whose breasts presented the areola, with all the characters we had described. We immediately saw her, and on examining her breasts we pronounced at once that there was the true areola of pregnancy—an announcement which she heard with the most fiery indignation, declaring that she would submit to any thing rather than lie under so calumnious an aspersion, and even consenting to permit an examination per vaginam, when proposed to her as the only thing which could save her character. On making the examination we were distinctly able to feel the fœtus by *ballottement*. She afterwards acknowledged that she had been "walking by moonlight with a young man who had a great regard for her."

If a woman has been pregnant before, and particularly if she suckled or is nursing, it may greatly embarrass our investigation. The colour of the areola depends on the deposition of an actual pigment between the cuticle and subjacent skin. Of this we have satisfied ourselves by making preparations of the part, one of which, showing this very distinctly, is preserved in the writer's museum. In some persons of fair complexion especially, this colouring matter is removed in some time after delivery, and the breast resumes its virgin appearance; in others the colour remains permanent, and there is even a slight prominence of the little glands to be observed sufficient to deceive an inexperienced eye. It is also to be recollected that it is peculiar to some young females to have the areola assume a shade of colour resembling that which we so frequently observe around or under the eyes.

The conclusion which Gooch came to on this subject was, that "darkness of the areola rarely depends on other causes (than pregnancy), and that, when it exists, it may generally be looked upon as a sign either that the patient is pregnant or has been so formerly." (Account of Female Diseases, p. 205.) It seems remarkable that so accurate a writer as Gooch should have confined his description to the colour alone. Smellie's account is more accurate, and he considers it as the result of pregnancy only. (Treatise on Midwifery, vol. i. p. 191.) William Hunter has not, as far as we are aware, left us any description of what he considered the true areola, but he professed such faith in this sign as to assert that he could always judge by it whether a woman was pregnant or not, and on one occasion gave a remarkable proof of his accuracy. Happening to examine the breast of a subject brought to him for dissection, he immediately pronounced from the appearance of the areola, that the woman had died pregnant: however, on examining the genitals, the hymen was found entire, but Hunter persisted in his opinion, declaring that the areola was more convincing than the presence of the hymen. The body was opened, and an impregnated uterus confirmed the justice of his assertion.

Since writing the above, a case has come under the writer's observation which greatly strengthens his reliance on this sign. We were requested to see a patient affected with menorrhagia, arising, as was supposed by her medical attendant, from disease of the uterus. The history of the case was briefly this:—the patient was near forty years of age, and had borne five children; in the May preceding she had miscarried in the fifth month, and the placenta was retained eight weeks. In July she returned to her husband's bed, but her health continued feeble, and she had at irregular intervals of one, two, or three weeks, profuse and foul uterine discharges, but had none of the usual symptoms which used to accompany her pregnancy in former instances, so that she utterly disbelieved in the possibility of her being then with child. For two months previous to our seeing her, her fears had been much augmented by the presence of a tumour in the centre and lower part of the abdomen, which was almost constantly the seat of severe pain; and she had still the foul uterine discharges. Under such circumstances we entertained but little idea of the existence of pregnancy, but on seeing her breasts we were rejoiced to find them full, and exhibiting a very perfect example of the true areola, with all its characters so well marked that we did not hesitate

to declare our belief that she was pregnant, though every other circumstance conspired to render it more than improbable. The uterine tumour felt as hard as cartilage, and knotty all over its surface, was very painful, and exquisitely tender to the touch; but the condition of pregnancy was put beyond a doubt in less than a week afterwards by her expelling a fœtus of five months, and along with it its placenta quite perfect, and afterwards several pieces or fragments of a substance resembling decidua, mixed up with what appeared to be portions of placenta and membrane, but altered in their texture and consistence so as to possess the toughness of leather.

Could these have remained in utero from the time of the former miscarriage? They certainly were totally different from any of the parts of undoubtedly recent formation. The expulsion of them went on for fully half-an-hour after the rest of the process was completed, and portions continued to be discharged for some days; after which the patient recovered well, and at the end of a month there was not a trace of uterine irritation or discharge, and she considered herself in better health than she had been for a year before.

[But although the state of the areola constitutes one of the best single proofs of the existence of pregnancy, it is obvious, that for accurate discrimination, it is necessary to be aware of the hue, in each particular case, in the unfecundated state. Moreover, instances are on record of a well-marked areola in persons who were not pregnant, as well as of an entire absence of areola in those who were. Dr. Guy (*Principles of Forensic Medicine*, p. 72, Lond. 1843) states, that Dr. John Reid showed him a case of enlarged mammæ, with distinct areolæ and mucous follicles, in a female, who had never been, and was not at the time, pregnant. (See Dr. Reid, in *Lond. Lancet*, Dec. 22, 1838.) The writer has had numerous opportunities for appreciating the insufficiency of these evidences when taken singly.]

Milk in the Breasts.—The secretion of milk in the breasts is popularly esteemed as an infallible proof of pregnancy, but nothing can be more erroneous than such a presumption, which is contradicted by facts, recorded on the best authority, proving the possibility of its formation under circumstances totally independent not only of pregnancy but even of intercourse, and at ages antecedent to puberty, and after the cessation of the generative faculty.

Perhaps the most remarkable case on record is that of the little girl of Alençon, who was produced by Baudelocque (Art d'Accouchement, tom. i. p. 188. ed. 1822) before the Royal Academy of Surgery on the 16th Oct. 1783, where she milked her breasts in presence of the members. This girl was only eight years old, and the secretion was caused by the repeated application of an infant which her mother was suckling at the time.

Belloc (Cours de Méd. Légale, p. 52) mentions a servant girl, who, being obliged to have sleeping in her chamber an infant which was being weaned, and which by its crying disturbed her rest, bethought her of giving it her breast to appease its clamour; and the result was that in a short time she had milk enough to satisfy the child. Foderé mentions having seen a lady, who, in order to escape being imprisoned, pretended that she was a nurse when she was not, and she succeeded in producing milk from her breasts. (Traité de Méd. Lég. vol. i. p. 440.)

The same phenomenon has occasionally occurred in women advanced in years. The following case is related by Mr. George Semple. (North of England Med. and Surg. Journ. vol. i. p. 230.) "Mrs. B. wife of John Breward, Simpson Green, near Idle, aged forty-nine, the mother of nine children, the youngest of whom is twelve years old, lost a daughter-in-law about a year ago, who died in about a fortnight after giving birth to her first child. On her death, Mrs. B. took charge of the infant, a little puny, sickly baby. The child was so fretful and uneasy, that Mrs. B. after several sleepless nights was induced to permit the child to take her nipple into its mouth. In the course of from thirty to thirty-six hours she felt very unwell, her breasts became extremely painful, considerably increased in size, and soon after, to her utter astonishment, milk was secreted and poured forth in the same abundance as on former occasions after the birth of her own children. The child, now a year old, is a fine, thriving, healthy girl, and only a few days ago I saw her eagerly engaged in obtaining an apparently abundant supply of healthy nourishment from the same fountain which nearly twenty years ago poured forth its resources for the support of her father." Several other instances still more remarkable are on record. (See Smith, Forensic Medicine, p. 484; Beck, p. 75, note; Philos. Trans. vol. ix. and vol. xxxi. Capuron, p. 126.)

[The writer, in another work, (*Human Physiology*, 5th edit. ii. 437, Philad. 1844,) has referred to many such cases; and to several occurring in the male. One of the most striking was communicated to him by Professor Hall, of the University of Maryland. The subject of it—a coloured man, 55 years of age—was exhibited to the obstetrical class in the year 1827. He had large, soft, well-formed mammæ, rather more conical than those of the female, and projecting fully seven inches from the chest, with perfect and large nipples. The glandular structure seemed to the touch to be exactly like that of the female. This man, according to Professor Hall, had officiated as wet-nurse, for several years, in the family of his mistress; and he represented, that the secretion of milk was induced by applying the children, entrusted to his care, to the breasts during the night. When the milk was no longer required, great difficulty was experienced in arresting the secretion. His genital organs were fully developed.]

Another source of deception might arise from the fact that women sometimes after nursing retain milk in their breasts for a great length of time. The writer is at present in attendance on a lady, who, after weaning her last child, which she nursed for fifteen months, retained *for nearly three years* so much milk in her breasts that she was obliged to adopt precautions to prevent her dress being wet by it. The child is now five years old, and she can still express a little milk from the nipples; she has not conceived since the birth of that child, but has always menstruated regularly. Dr. Francis, in his edition of Den-

man, (Francis's Denman, p. 229,) mentions, on the authority of Professor Post, that "a lady of this city (New York) was almost fourteen years ago delivered of a healthy child; since that time her breasts have regularly secreted milk in great abundance, so that, to use her own language, she could at all times easily perform the office of a nurse. She has uniformly enjoyed good health, is now about thirty-five years of age, and has never proved pregnant a second time, nor had any return of her menses."*

"We see," says Foderé, "women who have milk in their breasts from one pregnancy to another, and even for whole years together, although they have not nursed." And he adds that he has had repeated opportunities of observing the secretion of milk take place on the cessation of the catamenia at the turn of life, of which fact he quotes two striking instances. (Médecine Légale, tom. i. p. 440-1 and note.)

It has been already remarked that morbid causes capable of distending the cavity of the uterus may excite the sympathetic changes in the breasts, and it appears that even the secretion of milk may be thus induced, as happened in two cases mentioned by Frank, where it occurred in one in consequence of physometra, (Vol. iv. p. 50. French translation,) and in the other from hydrometra. (P. 182, ibid.) Notwithstanding, however, the exceptions established by such facts as the foregoing, we should attach great consequence to the presence of milk in the breasts, and if found in connection with others of the rational symptoms of pregnancy, it ought to go a great way in confirming our belief in the existence of that condition, especially if occurring in a woman who had never borne a child or been pregnant before.

Quickening, and motions of the fœtus.—By quickening is generally understood the first sensation experienced by the mother, of the life of the child within her womb; and a notion is very generally entertained in society that it is on the occurrence of this phenomenon that the child becomes for the first time endowed with life.

It appears very unaccountable that such an absurdity should have received not merely the sanction of popular belief, but that it should form the grounds of law in most civilized countries, our own not excepted; for the English law adopts the distinction, and considers the fœtus before quickening as inanimate, or merely as *portio viscerum matris*, but as afterwards endowed with life; and on this principle acts in the award of punishment for crime. Thus in a law enacted in 1803, called the Ellenborough Act, it is ordained that if any person shall wilfully or maliciously use means to cause or procure abortion in a woman *not quick with child*, he shall be declared guilty of felony, and may be fined, imprisoned, set in the pillory, publicly whipped, or transported for any term not exceeding fourteen years; but if the offence be committed *after quickening*, it shall be punishable with death.† In like manner, when a woman pleads pregnancy in bar or stay of execution, the court orders an investigation as to whether she is *quick with child* or not, for being merely pregnant will not be sufficient;‡ and if she be pronounced *quick with child*, execution shall be stayed until either she is delivered, or proves by the law of nature not to have been with child at all. In France the law is at once more merciful and more consistent with the laws of nature and with common sense, when it provides that "if a woman condemned to die states that she is pregnant, and if it be proved that she is so, she shall not suffer punishment until after her delivery."§

It is perfectly monstrous and absurd to suppose for a moment that the fœtus does not enjoy vitality from the first moment of its existence, and of course long before the sensation of quickening is felt by the mother; and if it be asked why no indications of life are given before the time at which quickening generally takes place, the obvious answer is, that the absence of any consciousness on the part of the mother relative to the motions of the child is no proof whatever that such motions do not exist.‖ Of this fact the writer can speak with certainty. A married lady, who menstruated for the last time on the 10th of November, came to Dublin in March, on the 21st of which month a consultation was held to determine whether she was labouring under a disease of the womb or not, as she had been previously assured by her medical attendant that she could not be pregnant because she had not sick stomach, nor felt the child. On examination the writer distinctly felt through the abdominal parietes the limbs of the fœtus in motion, as did also Mr. Cusack and Dr. Marsh, and yet the lady herself had no consciousness whatever of any such sensation, nor did she *quicken* till the second week of the following month, April, and was delivered of a healthy boy on the 9th of August.¶

In attempting to make a knowledge of this phenomenon available in any inquiry as to the existence of pregnancy, even where there cannot be supposed any intention or motive on the part of the woman to deceive, we obviously labour un-

* The last mentioned particular in this case is in accordance with the aphorisms derived from Hippocrates: Si mulier, quæ nec pregnans nec puerpera est, lac habet ei menstrua defecerunt," which is, however, shown to be incorrect by the perfect regularity of the catamenia in the case under the writer's observation.

† This law has been, and I think justly, designated as immoral, unjust, and irrational; as tempting to the perpetration of the same crime at one time which at another it punishes with death; while in the words of the admirable Percival, "To extinguish the first spark of life is a crime of the same nature both against our Maker and society, as to destroy an infant, a child, or a man; these regular and successive stages of existence being the ordinances of God, subject alone to his divine will, and appointed by sovereign wisdom and goodness as the exclusive means of preserving the race and multiplying the enjoyments of mankind."—Percival's Works, vol. ii. p. 430, 1.

‡ "Here again the law of the land is at variance with what we conceive to be the law of nature; and it is at variance with itself, for it is a strange anomaly that by the law of real property, an infant *en ventre sa mère* may take an estate from the moment of its conception, and yet be hanged four months afterwards for the crime of its mother." Paris and Fonblanque, vol. iii. p. 141, note.

§ Code pénal, art. 27. See Foderé, tom. i. p. 428. See cases already detailed under the first section of this article.

‖ Vide Beck's Medical Jurisprudence, p. 137. Gardien, Traité des Accouchemens, tom. i. p. 508.

¶ It may be observed here that the facts of this case are completely in opposition to the explanation of quickening given by Dr. Royston and others, who suppose it to be coincident with, and resulting from, the sudden ascent of the uterus out of the pelvic cavity.

der this disadvantage, that except we are at the time able to feel the motions of the child, we can have no evidence except her statement as to the fact of quickening or otherwise; and nothing is more certain than that she may be completely mistaken on both sides of the question. We have just mentioned a case in which motion of the child perceptible to the hand of another was not felt by the mother; and a second instance of the same kind has occurred to us lately in the wife of a medical friend. On the other hand, the examples of women who have supposed and firmly believed that they had quickened when no such thing had occurred, are numerous even to notoriety. We remember being some years ago called in great haste to see a lady, the mother of seven children, who was said to be in premature labour at seven months and a half, accompanied with hemorrhage. On our arrival, her husband, who was a physician, mentioned among other things that she had quickened at four months and a half, and had from that time continued to feel the child as distinctly as in any of her former pregnancies, adding *that he had himself repeatedly recognised its movements also;* on examination, however, we could discover no child in utero, and the case terminated in the expulsion of a few coagula from the uterus without any fœtus whatever. We do not, however, mean to have it inferred that we should not pay any attention to the statements of married women on this subject: on the contrary, we should attach great value to the assertion of a person who has already, and perhaps repeatedly, experienced the sensation, and has at the same time no conceivable reasons for wishing to deceive; but for the reasons already stated, we cannot yield implicit credence to such representations, they may be mistaken, or they may have strong and powerful motives to misrepresent, known only to themselves. In cases of criminal, or even ordinary legal investigations, there is always a motive to influence the representations made by the woman, and we can only give credence in proportion as the account may appear to us to correspond to other circumstances or conditions of the case, of which we are satisfied. Should we be able to feel the movements of the fœtus, of course we could have no doubt on the subject; but it must not be forgotten that such an examination is liable to be unsatisfactory, or even lead us into error if great caution be not observed. It may be unsatisfactory, because it not unfrequently happens that even in women who have really quickened, and have been for several weeks conscious of the motions of the fœtus, we are unable either to feel the child or recognise its movements. The writer is at this moment in attendance on a lady who quickened more than six weeks ago, and is now in the sixth month of pregnancy, and after repeated examinations neither we nor her attendant physician have been able to feel the fœtus. In another case, in which ascites was combined with pregnancy, which had advanced to the seventh month, it was found impossible to feel the child by any mode of examination that could be adopted, though it was made with great care, both internally and externally, by the writer, and by one of the most experienced practitioners in Dublin. This case gave rise to great embarrassment, and recourse was repeatedly had to the application of the stethoscope in the most skilful hands; but neither the pulsation of the fœtal heart nor the placentary murmur could be heard, though it happened that several times during our examinations the woman assured us that she was at that moment sensible of active movements of the child. Desormeaux tells us of a patient of his who felt her child at the ordinary period, and its movements continued remarkably strong for three weeks, after which they ceased for a whole month, and nothing could excite them: the child was born alive and healthy. (Dict. de Médecine, tom. x. p. 399.) On the other hand we may fall into the error of supposing we have felt these movements, when in reality the woman is not pregnant at all. One such instance we have already detailed, and more recently we met with another. Dr. Dewees relates a very marked instance of such an error occurring to himself. A young lady had her menses suppressed for several months; her belly swelled very much, her breasts became enlarged, she had nausea and vomitings in the mornings; in short she had all the usual symptoms of pregnancy. "Examining the abdomen carefully," says Dr. Dewees, "I found it considerably distended; there was a circumscribed tumour within it, which I was very certain was an enlarged uterus. While conducting this examination, *I thought I distinctly perceived the motion of a fœtus.*"* Another source of error would of course be found in a power which it is asserted some women possess of simulating the motions of the child by certain actions of the abdominal muscles. We never met with any such case; but Dr. Blundell, who mentions the fact, tells us of "a woman who was seen by the late Dr. Lowder and other eminent accoucheurs, who simulated these movements so exactly, that, had they judged from this sign alone, they would have pronounced her pregnant." (Lectures on Midwifery, p. 251.)

We must now turn our attention to the period of pregnancy at which we may in general expect that this phenomenon shall have occurred. Experience has shown that it happens from the tenth to the twenty-fifth week; but according to the writer's experience, the greatest number of instances will be found to occur between the end of the twelfth and sixteenth weeks, or, adopting another mode of calculation, between the fourteenth and eighteenth week after the last menstruation. And under ordinary circumstances, when quickening does occur, but especially if it happens in conjunction with the sudden ascent of the uterus out of the pelvis, the woman is apt to feel an unusual degree of nervous agitation, which not unfrequently ends in faintness or even complete syncope, after which she is sensible of a slight fluttering sensation, which from day to day becomes more distinct, until she fully recognises the motions of the child. The earliest instance of which we were certain was in the case of a lady, who must have conceived on the 10th of November, and she quickened on the 28th of January, the interval being eleven weeks and two days; delivery oc-

* Essays on several subjects connected with Midwifery, pp. 337-8. The case eventually proved to be one of accumulation of menstrual fluid in the uterus.

curred on the 17th of August. A very general impression prevails in society, that quickening takes place exactly at the end of four calendar months and a half, whereas in fact the greater number of instances occur two or three weeks before that time has arrived, and many also not till long after. We have already mentioned one such case, and have by us notes of several others. At this moment we are in attendance on a lady who has in seven successive pregnancies felt the child for the first time in the sixth month, and once in the seventh. Baudelocque mentions that some of his patients did not quicken until after the sixth or seventh month, and, "in one of these women," he adds, "whatever we could do, and notwithstanding the very obvious ballottement of the child in utero, which we could perform by a finger introduced into the vagina, its motions could not be ascertained either by the mother or the accoucheur who examined her, till the end of the seventh month. (Art d'Accouchement, ed. 1822, pp. 205-6.)

"There are some cases," says Johnson, "where the motions are not felt till near the end of the reckoning." (New System of Midwifery, p. 102.)

A fact much more remarkable than the occasional postponement of this change is its total absence during the whole period of gestation, notwithstanding the subsequent birth of living and healthy children. Two instances of this kind came under our own observation, and the fact is mentioned by several writers of authority. Levret speaks of a woman who felt no motion of her child in two successive pregnancies. "I was several times consulted," says Baudelocque, "about a woman whose pregnancy appeared doubtful to her till the last moment, as well as to the physician, because the motions of the child could not in any way be perceived; and nothing that we could do even at eight months and a half could excite them: the child, however, was born healthy, and as strong as usual." Gardien met with two such instances; (Traité des Accouchemens, tom. i. p. 509;) and Gooch says on this subject, "there are cases, though rare, in which the child has not moved during the whole of pregnancy, although has been born alive and vigorous: of this I have known one instance, and read of others.*

When we wish to feel or excite the motions of the child in utero, we may expect to succeed by adopting either such a manual examination of the abdomen as we are accustomed to make when examining for a tumour in that cavity, pressing with the fingers backwards towards the spine, or from each side towards the centre; or applying one hand firmly against the side of the uterine tumour, we impress the opposite side quickly with the fingers of the other hand.

Sometimes the simple application of the spread hand over the front of the abdomen is sufficient for our purpose; at other times we shall best succeed by the sudden application of the hand previously rendered very cold by immersion in water, or contact with a marble chimney-piece: this frequently has the effect of making the fœtus as it were start, and communicate a very distinct sensation of its movements.

It is obvious that there are two species of movements of the fœtus which may thus be recognised, one of which depends on the exertion of its muscular power, and of course implies life; the other, the result of mere change of place or situation, effected by some external agency, and capable of being recognised equally in the dead and the living fœtus: this latter, which is more properly mobility than motion of the fœtus, may be most effectually ascertained by a manœuvre, which has been named by the French ballottement, and which we shall describe fully under the section which treats of the state of the uterus.

Size of the Abdomen and state of the Umbilicus.—An increase in the size of the abdomen being the necessary result of the development of the uterus from pregnancy, a careful examination of that part will be essentially required in every instance of an investigation as to the existence of that condition.

When conception occurs, and the ovum is received into the cavity of the uterus, the organ increases considerably in weight; and its fundus becoming at the same time developed, and so presenting a broader surface for pressure from the superincumbent viscera, it descends lower into the cavity of the pelvis, and so will not, for the first two months, or sometimes more, produce any enlargement of the abdomen by its increased bulk. Such an enlargement, however, is frequently observed at this early period, but it will be found on examination to arise from an inflated state of the bowels, which very generally takes place soon after the commencement of gestation, and continuing for some weeks will cause the patient to look as large or even larger in the second month, than she will afterwards appear in the third or fourth. This inflated state of the bowels generally subsides after a month or six weeks, and then the patient will not appear enlarged at all, but, on the contrary, the abdomen may be found flatter than is natural to the patient, and the umbilicus under such circumstances will sometimes be found more depressed,† and as if drawn inwards and downwards, in which condition it is occasionally the seat of an unpleasant and rather painful sensation of dragging, the part being also at the time somewhat tender on pressure.

This state, however, soon begins to alter, and before the end of the third month the enlargement of the abdomen becomes obvious to the eye, and from this period continues to increase gradually from month to month in the same proportion as the development of the uterus proceeds. In the fifth month the depressed condition of the umbilicus begins to diminish, and by the end of the sixth month it is generally raised to a level with the surrounding integument, and afterwards it in many persons projects above the surface.

Such is the history of this change in the perfectly natural and healthy condition of the pregnant woman; but as there is, on the one hand, a host of causes which may produce enlargement of the abdomen, and be accompanied also by sev-

* Account of Diseases of Women, p. 203. Dr. Dewees also relates a similar case, "where the motions of the child were never perceived during the whole period of utero-gestation." Compendium of Midwifery, p. 105.

† This change is noticed by Velpeau, vol. i. pp. 175-6, and also by others. The French have a proverb which says, "en ventre plat enfant il a y."

eral others of the symptoms of pregnancy when it does not exist; so also, on the other hand, a woman may be with child, and yet the development of the abdomen not correspond to the period which has elapsed since conception.

When the enlargement proceeds from a gravid uterus, and four months of pregnancy have elapsed, if the patient be placed lying on her back, with her shoulders a little raised, and the limbs at the same time drawn upwards, so that the thighs shall be in a state of semiflexion on the trunk, and the abdominal muscles thereby relaxed, if the woman be not very fat we shall be able to feel and trace the outline of the gravid uterus, at a height in the abdomen proportioned to the period of pregnancy, as stated in the preceding section; and even though we should not be able, from the fatness of the woman, the tension of the abdominal parietes, or any other cause, to feel distinctly the uterine tumour and define its circumstance, we shall at least ascertain that the cause of the enlargement is something which renders the abdomen much more solid to the touch than is natural to that part, and an examination per vaginam detects the coexistence of the changes in the uterus, already described as necessarily accompanying gestation; while at the same time the general health of the woman is found unimpaired or unaffected by any symptom of disease.

When the increased volume of the abdomen is the result of morbid conditions, not affecting the uterus, as disease of the liver, spleen, &c., an ovarian tumour, or ascites, we shall, in general, without much difficulty form our diagnosis from the history of the case, the length of time the enlargement has existed, which may have greatly exceeded the whole term of gestation, the general diseased condition of the system, the total want of correspondence in the symptoms and conditions of the case if it were pregnancy; and, lastly, a vaginal inquiry assures us that the uterus is not enlarged.

When the abdomen is distended by the accumulations of fat in the omentum or in the integuments, or by the inflated state of the bowels, the very soft and yielding condition of the part under the hand when pressed backwards towards the spine, and the total absence of any solid tumour, together with the non-existence of the ordinary symptoms of pregnancy, will form a sufficient basis for an opinion. Should there exist ascites, that condition can hardly be overlooked or mistaken; but it must not be forgotten that pregnancy and dropsy may exist together, and, when they do, they may present a combination of circumstances of the most embarrassing description.*

Again, we must remember that there are women, who, from their height or some peculiarity of form, exhibit their increase of size much less than others, so that the abdomen will appear less at seven months than it generally does in the fifth month.† And it is still more important to recollect, that although pregnancy should exist, if the child die the development of the uterus will be arrested, and the enlargement of the abdomen will not continue to increase, but, on the contrary, will sometimes diminish, the dead fœtus being retained in utero for several months, and the patient, although really many months pregnant, may not exhibit any increase of size beyond what is natural to her; or being near the end of her nine months, may not be larger than she was at four or five. The writer lately saw a case of this kind, which gave rise to great doubt. In the month of May he was requested to see a lady who considered herself in the eighth month of pregnancy, and was rendered miserably solicitous about her condition because she had irregular discharges from the uterus, and felt no motion of the child. On examination her abdomen was found perfectly flat and even depressed, and no tumour of any kind could be detected in its cavity; but the uterus felt per vaginam was evidently enlarged and soft, and the os and cervix uteri had undergone the changes which accompany early pregnancy. The lady had begun to experience the symptoms of that condition in October, which continued till the beginning of January, when they suddenly ceased, and she became liable to vaginal discharges. All doubt about the case was solved shortly after the writer's visit by the expulsion of an ovum with a blighted fœtus, which had evidently not arrived at three months' growth, and during its long stay in the uterine cavity as an extraneous body had become encrusted with a reddish calcareous deposit.

With regard to the changes which take place in the state of the umbilicus, it is to be observed that any solid tumour enlarging the abdomen will also be capable of effecting the elevation of the umbilicus, which circumstance, therefore, of itself can afford us no certain information that the distending agent is a gravid uterus; but if, in a case in which pregnancy is supposed to be advanced to the seventh or eighth month, we find the umbilicus depressed and the belly flat, it will prove certainly that gestation has not advanced to such a period, although it will not be, as asserted by Dr. Gooch, decisive evidence against the existence of pregnancy, which may be present, but not sufficiently advanced to effect the change, or the uterine development may have been arrested by the death of the fœtus.

[**State of the Vagina.**—It has been affirmed by Dr. Kluge, of Berlin, and by M. Jacquemin, of Paris, that a bluish tint of the vagina, extending from the os externum to the os uteri, is a sure test of pregnancy. According to the former, this discoloration commences in the fourth week of utero-gestation, increases until the time of delivery, and ceases with the lochia. M. Jacquemin, on examining the genitals of prostitutes, in compliance with the police regulations of Paris, observed the same peculiarity of colour in the same situation in those that were pregnant: he describes it as a violet colour, or like lees of wine, and so distinct as never to deceive him,—being sufficient of itself, and independently of the other signs of pregnancy, to determine the existence of that state. M. Parent Duchatelet (*De la Prostitution dans la ville de Paris*, i. 217, 218, Paris, 1837,)

* See case related in the section on *Quickening and motion of the fœtus* in the present article.

† The writer was once called on to attend a young unmarried female of respectability, whom he found in labour, and he was assured by her mother that up to the hour of her labour she never suspected that her daughter was pregnant, not having perceived any alteration in her size; and the young lady had danced all night at a ball about a week before her delivery: she had completed seven months.

affirms, that he was present when M. Jacquemin's accuracy in this matter was successfully put to the test: in the investigation, he examined no less than 4500 prostitutes. Dr. Montgomery, however, (*An Exposition of the Signs and Symptoms of Pregnancy*, p. vi. Lond. 1837,)—from limited observation, it is true—found, that whilst in some cases the bluish colour was very obvious, in others it was so slight as to be scarcely, if at all, perceptible. There is nothing more probable—as the writer has remarked elsewhere (*Human Physiology*, 5th edit. ii. 420, Philad. 1844,)—than that the capillary circulation of the mucous coat of the vagina may be modified along with that of the interior of the uterus during pregnancy, so as to give occasion to a change of colour like that mentioned by the above-cited observers; but it may be doubted whether the test can be often available, especially in private practice.]

State of the Uterus.—Having thus carefully investigated the circumstances of the case as far as we can discover them either by the report made to us, or infer them by the presence or otherwise by the sympathies already enumerated, we proceed in the next place to an examination of the uterus itself, having for our object to ascertain the following points:—the state of the os uteri and cervix; the condition of the organ with regard to development, and the degree to which it may be enlarged; the correspondence of such degree of enlargement with the other circumstances of the case; the cause of its increase, and the nature of its contents.

1. *State of the os and cervix uteri.*—In the unimpregnated condition of the uterus, its mouth and the lower section of the neck, when examined by the finger introduced into the vagina, can be felt projecting into that cavity from a quarter to half an inch. The part so projecting feels remarkably firm, and about as large as the end of a man's thumb, having in its termination in the vagina a transverse opening, whose lips or margins feel firm and well defined. This may be so far open as to allow the extremity of the finger to be insinuated between them to the depth of an eighth of an inch, sometimes a little more, sometimes not so much; or it may merely communicate a sensation of a slight depression almost without a cavity, such as is felt when the tip of the finger is pressed between the lateral cartilages at the extremity of the nose. Sometimes the os uteri differs very considerably from this description, being almost imperceptible from its diminutive size, and perfectly circular.

When conception has taken place, all these characters begin to alter; the change from the natural condition above described being distinct in proportion to the period of gestation at which the examination is made. In order to fit the uterus for the reception of the ovum and its support, there is, very soon after impregnation, a greater supply of fluids directed towards it; its vessels, which before crept almost imperceptibly through its dense structure, and with their calibre completely constringed, become distended and carry blood; the cellular texture is loosened out, and its interstices are infiltrated with a greater quantity of fluid, and in consequence the organ becomes not only altered in texture, but increased in size and weight. At this time, when the finger is applied to its vaginal extremity, the cervix is felt fuller, rounder, and softer or more springy and elastic under the point of the finger; and the same alterations having taken place in the labia of the os uteri, this part communicates a corresponding difference in the sensation received by the finger of the examiner: the margins of the orifice feel tumid, but softer and much less distinct, having lost the well-defined edge, which in the unimpregnated organ is natural to them; while the orifice itself, instead of seeming transverse, feels as if it were circular, and admits the tip of the finger more readily and to a greater depth than in its former state. As pregnancy advances, other changes in these parts may be appreciated. During the sixth month for instance, we ascertain that the cervix has not only undergone the changes of structure already detailed, but that it has lost somewhat of its length, owing to a portion of its upper section, or that which unites it to the body of the organ, becoming dilated, and taken up as it were to form a part of the distended cavity containing the child; and this obliteration of the cervix from above downwards continuing to be gradually effected, we find, if we examine towards the close of gestation, that the projecting cervix is no longer to be felt, but in its place there is detected, at the upper extremity of the vagina, a globular tumour, which is the enlarged uterus, with the head of the child to be distinctly recognised through its parietes. In like manner also the os uteri undergoes great changes of form, structure, and position, as pregnancy advances.

During the greater part of the first three months, besides the alteration already mentioned, it is felt lower in the vagina, and not unfrequently projecting a little forwards; but as soon as the uterus begins to rise into the abdomen, and leaves the pelvic cavity, as it does by the fifth month at farthest, sometimes a month earlier, its fundus leans forwards, and in consequence the os uteri is directed backwards; its margins are now felt very soft and relaxed, and we distinguish very generally within the circle of its orifice the cervical glandulæ slightly projecting, and feeling like little firm smooth vesicles rolling under the point of the finger. We can now also introduce the finger with great ease to a considerable depth into the cavity of the cervix, owing to the very yielding condition of the labia of the os uteri. From this period, in consequence of the rapid development of the uterus, and the shortening of the cervix, the os uteri rises in the pelvis, and is of course removed farther and farther from the external parts, while, at the same time, the anterior projection of the uterus increasing, its mouth is in the same degree directed backwards, so that, if we examine in the eighth or ninth month, we reach it with difficulty, and must expect to find it in the direction of the upper part of the sacrum. If gestation be drawing to a close, the orifice will often be hardly distinguishable, and when felt gives only the impression of an opening in a nearly flat surface, without any elevated margin, or at most very little, and feeling as a mere rugous opening in the mucous membrane of the upper part of the vagina.

But we must recollect, when we come to form an opinion from the existence of such changes in the os uteri, that there are other conditions of the uterus besides pregnancy by which they may be produced so as to assume almost exactly the characters of those that accompany the earlier periods of gestation. Thus, for instance, the near approach of menstruation and the accompanying irritation of the uterus may (and we have had repeated proofs from examination that it does) effect such a change in the form and texture of the os uteri. The same thing will happen in a more marked degree, when the organ becomes from any cause enlarged either by an increase of its substance, or still more remarkably when its cavity becomes distended by an accumulation of fluid within it, as of blood or water, or the presence of a diseased growth, such as a polypus or hydatids.* Moreover, in some women, especially those who have borne several children, the condition of the os uteri is at all times such as may but too easily impose on us. On the other hand, however, there is one fact on the subject on which we may rely,—viz. that inasmuch as pregnancy must always be accompanied with the physical changes of structure in the uterus already mentioned, should we find in a suspected or doubtful case, especially if supposed to be of some months' duration, the os uteri retaining distinctly the characters which belong to it in its unimpregnated state, that is, its transverse orifice with well defined and firm margins, we may conclude with certainty that the woman is not with child.

2. *Size of the Uterus, &c.*—When conception has taken place, the uterus almost immediately begins to increase in size, generally in every part, in consequence of the new action already described, but especially at the fundus. Here the cavity begins to increase its capacity, to enable it to receive and accommodate the ovum, which being accomplished, the upper part of the organ continues to increase in size in proportion to the growth of its contents. The fundus is first developed, then the body, and lastly the cervix; the latter part not being affected by the process of expansion until about the sixth month, as already stated. During the earlier months, therefore, the finger introduced per vaginam cannot reach sufficiently far to arrive at and detect the development which has taken place in the upper part of the uterus; and as the increase of size in the organ is not as yet such as to prevent its being still accommodated within the pelvis, it cannot be detected by examining through the parietes of the abdomen; wherefore, during this period, which extends through at least the first three months, the development of the organ or its degree will be difficult to ascertain, but will become gradually more easy of detection as pregnancy proceeds and the uterus enlarges. In general, by the end of the fourth month, the fundus of the uterus may be felt, especially in a thin person, overtopping the anterior wall of the pelvis. During the fifth it rises to half-way between the symphisis pubis and the umbilicus; and if an examination be made per vaginam, we can detect the enlarged uterus, which we encounter when we attempt to pass the finger between the anterior part of the cervix and the inside of the symphisis pubis,—a situation in which, when a woman is not pregnant, and even during the earlier periods of pregnancy, we are not able to feel any thing. At this period, also, we may at the same moment feel the fœtus by ballottement, as described in another section. In the sixth month the uterus rises as high as the umbilicus, which is now for the first time sensibly affected and begins to rise to a level with the surrounding integuments. In the seventh month the fundus uteri may be felt half-way between the umbilicus and the end of the sternum; and if an examination be made per vaginam, the finger readily detects the globular tumour of the uterus resting on the symphisis pubis, and within it the child's head; but the os uteri is now reached with greater difficulty, both because it is raised absolutely higher in the pelvis, and also because it is removed farther from the external parts by being projected more towards the promontory of the sacrum.

By the end of the eighth month the uterus has risen as high as the ensiform cartilage, and fills the whole abdomen, which is now very prominent and tense, and the umbilicus is in general not merely on a level with the integuments, but projects a little beyond them.

In the ninth month the uterus continues to enlarge, but the degree of its increase is not very observable by an increased elevation of its fundus, which on the contrary very generally falls lower towards the close of the month, so that for a week, or even two, before labour, the woman will appear and feel smaller than she was previously. If at this period we examine internally, the os uteri will in most cases be touched with great difficulty from its situation towards the upper and back part of the pelvis; there are in general no remains of the cervix; and the margins of the os uteri are felt thin, soft, and so relaxed that the orifice would receive with perfect ease the end of one's thumb, and within its circle we may feel the membranes.

Now it is important to notice the different degrees of distinctness with which these changes in the uterus may be recognised in different individuals, or in the same individual at different times, and to speak of the best method of conducting the examination.

In some women there is a natural stiffness and tension of the muscles of the abdomen, which is a great obstacle to an examination; and this they can produce or increase at pleasure, if they wish to baffle us in our investigation. In this, however, we may defeat them, by engaging them at the instant in conversation on some subject connected with their case which will be likely to set them talking. In other cases a similar difficulty will arise from inflation of the intestines or their distention by an accumulation of fæces; or a still more formidable bar may be found in a general condition of *embonpoint*, when the omentum and abdominal integuments may be so loaded and thickened with fat, that we can no more feel any thing through them than if we had a folded blanket between our hand and the patient's abdomen. This is so remarkable in some fat women, that we have found it impossible immediately

* In introducing hydatids here, we do not mean to be understood as considering them distinct from pregnancy, from which we believe they always arise, but as distinct from the natural conditions of that state, and from the presence of a fœtus.

after delivery to ascertain by external examination the degree of uterine contraction, although there were other satisfactory proofs of its perfection. We should not forget that this is a state of the abdomen very apt to occur at the turn of life, when, from the cessation of the catamenia, women very often fancy or affect to think themselves with child. On the other hand, the examination will be most satisfactory in women of a spare habit, and who have the abdominal parietes relaxed.

It was before stated that during the first three months we cannot expect much information from the altered size of the uterus, but that after the lapse of another month, the change might be ascertained both externally and also per vaginam; and it may be here added that in a case of doubt we may make these two modes of examination mutually confirmative of each other, by applying the finger of one hand to the os or cervix uteri, and pushing that part upwards, and then with the other hand gently pressing down the tumour felt in the abdomen. If we thus feel its descent upon the finger in the vagina, it affords almost certain proof that the tumour is the uterus in a state of enlargement. But we must again recollect that a certainty even of this will not be sufficient to assure us of the existence of pregnancy, because the enlargement may arise from other causes than the presence of a fœtus, such as hydatids, polypus, dropsy, or accumulated menses within the uterus, or scirrhous thickening of its substance. In the case of polypus or scirrhus, the great solidity of the organ would at once undeceive us; but in other circumstances we might be able to ascertain merely that the cavity of the organ was increased in capacity without being able to determine the exact course of its enlargement. At the same time the presence of several of the symptoms of pregnancy might afford a very strong moral conviction of the existence of that condition; while, on the other hand, we may discover such a want of correspondence between the state of the uterus and the other symptoms apparently indicating a certain period of pregnancy, as would be sufficient to decide our opinion on the negative side of the question.

We have already spoken of the mode of examining externally to discover the presence of a fœtus in utero, and alluded to another form of examination per vaginam, to which we ought to resort for this purpose. As we have no English name for this mode of examination, it is still designated by its French name.

Ballottement.—This mode of examination is thus to be instituted. The patient may be examined in the upright position, or placed lying with the shoulders much raised. One or two fingers are then to be introduced into the vagina and carried upwards until their points are applied to the anterior section of the cervix uteri, and as high up on that part as they can be conveniently made to reach without using force, and they must be carefully kept in constant contact with the part to which they have been applied. The other hand of the examiner is to be placed on the abdomen over the uterine tumour, which should be pressed downwards towards the cavity of the pelvis; instantly on our doing this, the fingers which have been kept applied to the cervix should be impressed against it with a quick and slightly jerking motion upwards, when something will be felt to have bounded away from the fingers, upon which it will, in the course of three or four seconds, be felt to drop again with a gentle pat.

Should this be distinctly felt, it is proof positive of a fœtus in utero, there being no other condition or disease of the organ in which a solid body can be felt in this way floating in its cavity; and it possesses this great advantage over many other modes of investigation, that it is equally applicable to the dead as to the living fœtus. But we must be prepared for occasional disappointment in this test as in others, inasmuch as the most carefully conducted examinations of this kind have failed of success when there was really a fœtus in the womb of sufficient bulk to be thus felt, as we have ourselves experienced. This difficulty may arise in some cases from the fœtus being unusually small, or from the cervix being unusually long; and in some instances we were satisfied it has arisen from the uterus lying too much beyond the reach of the finger at the time of the examination.

The time at which we may resort to this examination with the best prospect of success is generally said to be from the fourth to the sixth month. Our experience leads us to say that it is not likely to be satisfactory until after the end of the fourth month, but from that till the end of the sixth it will be found most available, and often completely decisive.* In the earlier periods of pregnancy the fœtus is too light to be felt, and in the more advanced its presence is ascertainable by other means, and besides it is then too large and too much confined to be made to float or move about thus freely.

It is desirable that the bladder and rectum should be quite empty when we make this examination, that the uterus may have as much space as possible for its descent into the pelvis, and so be brought as much as possible within reach of the examiner's finger. We must be careful not to mistake the movement of the uterus for that of the fœtus, an error into which we shall be particularly liable to fall if we remove the fingers from their contact with the cervix while making the examination. In one instance of enlarged uterus we knew the pulsation of one of the arteries to be mistaken for the drop of the fœtus on the finger.†

Application of Auscultation.—Since the appearance of the memoir of Dr. Mayor (Vide Bibliothèque Universelle, Nov. 1818) of Geneva, in 1818, and the subsequent observations of Kergaradec and Laennec, the application of auscultation as a means of detecting pregnancy has been much cultivated, and with results highly benefical to the interests of science and our powers of making a correct diagnosis.

The phenomena thus ascertainable are, the pulsations of the fœtal heart, and a peculiar sound audible in that part of the uterus to which the placenta is attached, and hence called the placental sound or murmur (*bruit placentaire*). We

* Gardien specifies four months and a half; Gooch from the fifth to the seventh.

† On this subject see *Baudelocque*, tom. i. p. 206.—*Desormeaux*, Dict. de Méd. tom. x. p. 400.—*Velpeau*, Traité des Accouchemens, tom. i. p. 185—*Gooch*, On Female Diseases, &c. p. 215—*Gardien*, Traité Complet, &c. tom. i. p 507-10.—*Mahon*, Méd. Leg. tom. i. p. 160. note by Fautrél.

shall first consider the modes of investigating these, and then state the advantages which this mode of examination enjoys above others, and the defects under which it labours as a general means of diagnosis.

The placentary sound is the one first capable of being examined, and may be heard as soon as the uterus has become sufficiently developed that its fundus shall have risen above the anterior wall of the pelvis: this happens in the fourth month of gestation, before which period we do not believe the placental sound can be ascertained. We are aware that cases are recorded in which it was supposed to have been heard so early as the tenth week. If so, we have not been so fortunate as others, although we have very many times indeed carefully repeated our examinations, but never succeeded until four months of pregnancy had been completed.*

The characters of this phenomenon are, a low murmuring or somewhat cooing sound, resembling that made by blowing gently over the lip of a wide-mouthed phial, and accompanied by a slight rushing noise, ("Battement simple avec souffle." —*Kergaradec,*) unaccompanied by any sensation of impulse. This sound is in its returns exactly synchronous with the pulse of the mother at the time of examination, and varies in the frequency of its repetitions with any accidental variations which may occur in the maternal circulation. Its situation does not vary during the course of the same pregnancy; but in whatever region of the uterus it is first heard, it will in future be found, if recognised at all, for it is liable to intermissions; at least we shall occasionally be unable to hear it where we have already heard it a short time before, and where we shall shortly again recognise it. In relation to the regions of the abdomen, its seat will of course vary in proportion to the progressive advance of the pregnancy. According to our experience it will be most frequently heard about the situation of the fallopian tube of the right side, but it may be detected in any of the lateral or anterior parts of the uterus.

[It is questionable, however, whether this sound be ever produced except by pressure on the large dorsal vessels of the mother. It is, indeed, positively affirmed, that the sound has been heard in cases of uterine and other tumours where there was no pregnancy. (Raciborski, *Manual of Auscultation*, by Fitzherbert, p. 145, Lond. 1835. E. Rigby, *System of Midwifery*, Amer. edit. Philad. 1842. Hope, *Treatise on Diseases of the Heart*, by Dr. Pennock, Philad. 1842: and Prof. Huston, in Amer. edit. of Churchill's *System of Midwifery*, p. 136 (note), Philad. 1843.) In one case of fibrous tumour of the uterus, the writer heard it distinctly.]

The other phenomenon differs in every one of its circumstances from the placentary murmur. It results from the contractions of the fœtal heart, which, when conveyed to the ear, are heard as rapid pulsations without any of the murmuring sound of the *bruit placentaire.* These pulsations vary in number from 120 to 160 in the minute, while the mother's pulse at the same time may not exceed the usual standard; and should it happen to do so, the pulsations of the fœtal heart will not be found similarly affected. By this want of correspondence, and permanently greater rapidity, they are distinguished from the pulses of the mother. The impulses of sound communicated to the ear are in general very delicate and feeble, resembling very much the ticking of a watch heard through one's pillow at night.† This phenomenon is not ascertainable, according to the writer's experience, until five months of pregnancy have been accomplished,‡ and then requires for its recognition very great attention on the part of the examiner, and also a practised ear. As pregnancy advances, the sound becomes more distinct. Its seat or source being the heart of the fœtus, and the fœtus having in most women a great disposition to change its posture, the situation of the sound will consequently be different at different times, especially from the sixth to the eighth month. It is, however, most frequently and most readily heard at one or other side, and at about the middle of a line drawn from the umbilicus to the anterior and inferior spinous process of the ileum, and more frequently at the left side than at the right.

The mode of ascertaining the existence of pregnancy has this great advantage over almost every other, that it detects not only the presence of a fœtus, but proves its life also. On the other hand, however, should life be extinct, auscultation cannot possibly afford us any information; and here lies the great defect under which its application labours when compared with other modes of examination, to which also it is inferior in not being available during that period of pregnancy which is most obscured by doubt. Again, from the fact that both phenomena are occasionally inaudible (see case related in the section on *Quickening*, &c.) even in the case of a living and healthy fœtus, it will not justify us in giving a negative opinion. The bruit de cœur once heard is of course decisive, because there is no other sound which can be mistaken for it; but not so with the placental murmur, which may be so imitated, either artificially, as by pressure, or by disease, that the nicest and most practised ear cannot detect any difference. A case most strikingly illustrative of this statement was not long since under the writer's care, in which enormous enlargement of the uterus, of that kind which has been called vascular sarcoma, was accompanied by this phenomenon in its most perfect condition; and in another case of abdominal tumour (supposed to be of the spleen) pressing on the aorta this sound was equally distinct: moreover, it may at any time be imitated by pressing the end of the stethoscope over the region of the iliac vessels.

At all times this kind of examination requires great care and niccty on the part of the examiner, and complete silence around him, for the sounds are very often almost imperceptible. We have

* "Je ne l'ai rencontré que dans la seconde moitié de la grossesse. Si Laennec et M. de Leus, qui disent l'avoir reconnu avant la fin du troisième mois, ne se sont pas mépris, il me paraît par cela seul impossible de l'attribuer à la circulation utéro-placentaire." *Velpeau*, Traité des Accouchemens, vol. i. pp. 190-1.

† "—semblable à celui que font entendre les battemens d'une montre enveloppée de beaucoup de linges." *Velpeau.*

‡ "Ces pulsations s'entendent distinctement des le sixième mois, et quelquefois même un peu plus tot." *Laennec*, tom. ii. p. 457.

the very highest authority for believing that the formation of a correct judgment by their means requires more care, and is beset with greater difficulties than are found in investigating all the diseases of the chest.* We must recollect that, from their occasional intermission, it may happen that we shall not be able to give a satisfactory opinion until we have several times repeated our examination. To make this examination, it is by no means necessary that we should be practised stethoscopists, or even use the stethoscope at all, since the naked ear will detect the sounds sought for with perfect accuracy; but the use of the tube is for many reasons preferable.

It appears not unimportant to mention here, that our success will sometimes depend on our making a proper degree of pressure with the end of the instrument, since the seat of the sound which we seek to discover may not, and very often is not, in contact with the surface on which we apply our ear or our stethoscope; and under such circumstances the intervention of a fluid, such as the liquor amnii, will effectually prevent the transmission of the sound, until, by gently increasing the pressure on the integuments, we carry them inwards, and by displacing the intermediate fluid, whether air or water, we bring them into more immediate contact with the source of the sound, and obtain a solid medium for its transmission.†

Substances expelled from the Uterus. — The expulsion from the uterus of solid or organized substances, presenting occasionally very unusual or anomalous characters, excites not unfrequently suspicions of the existence of pregnancy in the unmarried, and perhaps the perfectly chaste. Under such circumstances we may be applied to for an opinion as to the nature of the substance expelled, and are expected to declare whether it is or is not the product of conception. Inasmuch as character and fair fame of the individual depend on our answer, the greatest care will be required in making such an examination, and the utmost caution in forming or pronouncing an opinion. To this duty no person can possibly be competent if he have not previously made himself intimately familiar with the appearance and structure of the ovum, particularly in the earlier periods of its formation; and this knowledge he may take it for granted he never will attain to by descriptions in books or plates, nor by any means except repeated examinations of the structure itself under every circumstance and condition in which it may be found: more especially when it is altered in its characters, as it usually is, by abortion.

The substances thus expelled may be, 1. an early ovum; 2. a mole; 3. uterine hydatids; 4. the membrane produced in dysmenorrhœa; to each of which we shall now turn our attention.

1. *An early Ovum.* — When the product of conception is expelled within a month from the time of conception, the most careful and skilful examination may fail in detecting its true character. After this period its structure is sufficiently distinct to be recognised by any one well acquainted with it, and who will take *sufficient time* to examine it; for this also is absolutely essential to the formation of a correct opinion. The ovum, when thus expelled, is generally infiltrated with firmly coagulated blood, and the pressure which it sustains while it is forcing its way through the contracted and rigid cervix of the uterus, so condenses its texture as to reduce it apparently to the condition of a solid homogeneous mass. The real structure of the body cannot be ascertained by any examination instituted at the moment, but must be gradually made out by first immersing the substance in water for a day or so; and then, by agitation and washing, the coagulated blood must be removed, while with delicate blunt instruments we gently separate the component parts of the

* "L'étude des phenomènes dont nous venons de parler dans cet article demande incomparablement plus d'attention que celle de tous ceux que présentent les maladies de la poitrine." *Laennec*, tom. ii. p. 466.

† The author of the article AUSCULTATION in the first volume of the present work, gladly avails himself of the present occasion to correct some mistakes which he has committed in respect to the appropriation of certain opinions therein advanced.

In treating of the utero-placental circulation, with reference to the variety of sounds which accompany it, we gave it as *Dr. Ferguson's* opinion that "the most constant variety is a combination of the bellows or sawing, with the hissing sound, commencing with one of the former and terminating with the latter;" and in another place we stated that "*Dr. Ferguson* had not observed any variety of the sounds to be peculiar to particular stages of pregnancy." Now the fact is that both these remarks belong to *Dr. Kennedy*, and are taken from an excellent paper by this gentleman, published in the fifth volume of the *Dublin Hospital Reports*. In transcribing the extracts which we had made, we inadvertently inserted Dr. Ferguson's name in place of Dr. Kennedy's, and referred to a paper by the former gentleman in the *Dublin Medical Transactions*, from which we also had been making extracts. We are much obliged to Dr. Kennedy for having enabled us to correct our mistake.

In respect of certain other statements made by us in the same article, we most readily afford Dr. Kennedy the opportunity of giving his own explanation by extracting a passage from a communication with which he has favoured us.

Extract of a letter from Dr. Kennedy to Dr. Forbes:

"You appear to have misunderstood me when you state 'there seems little ground for believing with Dr. Kennedy that the placental arteries themselves have a share in the production of the sound any farther than by their action promoting that of the uterine arteries.' Now if you will refer to p. 241 of my paper you will find that I merely deem it possible that the passage of the blood through the arterial tubes and cells of the *maternal part* of the placenta may have *some effect* in producing it; and p. 244, in speaking of the *possibility* of its operating so, add that the point *still admits of doubt*. From this it will be seen that I by no means commit myself, either in the manner or to the extent that your statement implies. The fact is, that although my explanation may not have been sufficiently explicit on this point, yet the manner in which I endeavoured to explain the maternal part of the placenta's assisting in producing the soufflet (if it did so at all), was that which you more distinctly state, namely, by promoting the action of the uterine arteries. But even of this I was not, nor am I as yet quite satisfied. I however thought myself called upon candidly to state facts and inferences as they presented themselves to me on my investigation, leaving it to others to draw what conclusions they thought proper from them.

"There is still another point to which I wish to draw your attention, as, from the manner in which you quote me, my meaning is very equivocally conveyed. You say, 'Dr. Kennedy denies M. Ollivry's statement, that the soufflet is immediately extinguished on the removal of the placenta, the death of the fœtus, and the tying the cord, the sound becoming abrupt,' &c. From this it might be concluded that I stated the soufflet always to continue after delivery, death of the fœtus, &c. an inference widely at variance with the fact, and such as was never intended by me. You will find, p. 244, Dub. Hos. Rep. vol. v. the passage which you quote: it runs thus: 'Neither does the sound (the soufflet) *invariably* cease, as we might be led to conclude on the authority of Dr. Ollivry, on the separation or expulsion of the placenta; but provided the uterine arteries at this part, from imperfect contraction of the uterus, continue pervious to blood, a soufflet will still continue,' &c. Here you will at once perceive how much the words 'immediately extinguished,' in place of 'invariably cease,' affect the nature of the statement."

May, 1833. J. F. *Edit.*

mass *under water*, until at length we ascertain its real character. This process may occupy us for a time varying from three or four days to a week, before we are able to satisfy ourselves perfectly. Haste may completely defeat the object of the examination.

If in the progress of such an investigation we discover a fœtus, or even a part of one, it would of course be decisive; but this may not be the case, and yet we may recognise all the other component parts of the ovum presenting several structures which are never produced by disease.* First, we may have the decidua covering either partially or completely the substance under examination, distinguished by its soft, rich, pulpy appearance and strong red colour, its external or uterine surface rough and unequal, and, when well freed from the coagulated blood, exhibiting numerous small round foramina, (see Hunter's plates of the gravid uterus, xxix. fig. 11, and also plates xxviii., xxx., xxxiii., xxxiv.), capable of admitting a pin: its internal surface is smooth, and exhibits little or no appearance of these openings. This coat may be found attached to the ovum, or entirely torn away and separated from it during its expulsion; but in either case these characters mark the true decidua, and are not found in the products of disease. Within this outer coat another is found immediately investing the membrancs of the ovum, the outer surface of which is smooth, and its inner completely filamentous, receiving the beautiful arborescent villi which cover and shoot from the surface of the chorion, forming the bond of union between it and this inner decidua. The discovery of these arborescent villi or capillaries is proof positive of the nature of the product, as they are never found presenting like characters, except upon the chorion or uterine surface of the placenta.

2. *Moles.* — With regard to those solid fleshy masses called moles, which are occasionally expelled from the uterus, there is a great discrepancy in the opinions of writers of authority, some of whom maintain, with Mauriceau,† that they are the result of conception alone, and of course positive proofs of pregnancy; while others either think this very doubtful, or deny it altogether, and suppose that they are merely accidental formations of a morbid character. "By the term *mole*," says Denman, (Introduction to Midwifery, p. 124), "authors have intended to describe very different productions of, or excretions from, the uterus. By some it has been used to signify every kind of fleshy substance, particularly those which are called *polypi*; by others, those only which are the consequence of imperfect conception when the ovum is in a morbid or decayed state; and by many, which is the most popular opinion, every coagulum of blood which continues long enough in the uterus to assume its form, and to retain only the fibrous part as it is properly called, is denominated a mole." — "True moles," says Voigtel, (Hand buch der Pathologischen Anatomie, vol. iii. p. 501), "are distinguished from the false and other growths of the uterus by their not deriving their origin from the substance of the womb or its membrane; but by their being always the consequence of conception." This is at once assuming that conception is the sinè-quâ-non without which a mole cannot exist,—an opinion which is supported, to a certain extent at least, by the experience of Mr. Burns, who says, "It is the opinion of many that these substances are never formed in the virgin state, and no case that I have yet met with contradicts the supposition." (Principles of Midwifery, ed. 7, p. 111). Foderé (Médecine Légale, vol. i. p. 468) thinks that the true mole is always the result of intercourse between the sexes, and that those substances which are discharged from the virgin uterus are merely condensed coagula of blood, which of course may form in the chaste as well as others. Baudelocque (Art. des Accouchemens, tom. ii. p. 367) considers the mole and the false conception as one and the same.

On the other hand, we find the matter thus stated by Dr. Smith: "Moles are disorganized masses that form in the uterus; and continuing for some time to increase, cause some of the symptoms of pregnancy. They have been found in females who never had any intercourse with the other sex." (Principles of Forensic Medicine, p. 298). Ruysch makes a similar assertion, and adds that he has seen them in women so advanced in years as to be beyond the reach of suspicion. A case came before the parliament of Paris in 1781, in which the female sued for damages for seduction. Twenty months after this was alleged to have been committed, she brought forth a mole. The parliament decided against her on the score of character, and they added that "the causes of moles were as uncertain as the time of their gestation, *and that there were instances of girls, and even of nuns, who had produced moles without any previous criminal connection.*" Foderé, who quotes this case, disapproves altogether of the view taken by the court. (Médecine Légale, t. i. p. 478).

It is to be observed here that this is a mere question of fact, of which different views have been taken, and opinions formed by authors or practitioners according to the opportunities afforded them of judging. The writer does not feel prepared to undertake to reconcile these conflicting opinions, but it appears to him almost certain that much of the discordance has arisen from substances of very different characters having been indiscriminately classed together under the general term of moles, some of which were undoubtedly neither more nor less than diseased ova, or remnants of such, while others were as certainly either merely condensed coagula, or perhaps uterine polypi. Hence Mahon (Mahon, Médecine Légale, t. i. p. 274) appears perfectly justified in making the following remarks:—"The existence of moles properly so called is extremely doubtful, since they may all be referred to some one or other of the substances of which we have spoken, viz., a placenta which had continued its growth, the fœtus having perished; the degenerated remains of the after-birth; coagulated blood; sarcomatous

* See a case related by Mr. Lemon in the Edinburgh Medical and Surgical Journal, vol. xi. p. 96. The writer has in his museum more than one specimen illustrative of this absence of the fœtus where the other parts of the ovum exist.

† "Il est très certain que les femmes n'engendrent pas de moles ni de faux germes, si elles n'ont usé du coit." Maladies des Femmes, tom. i. p. 109. "Massa carnea, vasculosa, ex utero excreta. Ovum deforme." *Vogel.*

tumours or polypi of the uterus. The two first cannot exist except after sexual intercourse; the other three may be found independently of it.* This is the distinction which it is of the greatest importance to make in questions of legal medicine, that we may not without cause compromise the reputation of the unmarried girl or the widow of irreproachable life and conduct."

In this view the writer entirely coincides, and thinks the medical jurist would not be justifiable in pronouncing any such mass expelled from the uterus as proof of pregnancy, except he can detect in it either the fœtus or a part of it, or some other of the component structures of the ovum.† In the instances which have come under our immediate observation, the women were all either married or avowedly indulging in sexual intercourse, and the masses expelled, when examined, were found to contain the product of conception degenerated or greatly altered by disease. The last of these substances which came under our observation was expelled from the uterus immediately after the discharge of a healthy ovum, containing a well-formed fœtus of four months, at which period of pregnancy the woman, according to her own account, had arrived. The substance had the external characters usually considered as those of a mole, and was of the form and size of a large orange. When opened, no trace of a fœtus could be discovered, but there was a small remnant of an umbilical cord, which was ragged at its unattached extremity: the fleshy envelope varied in thickness from an eighth to half an inch, the thickest part being that where the placenta was situated, the internal surface of which exhibited very remarkably the tubercular disease represented in Denman's ninth plate. (It is preserved in the writer's museum.) Morgagni (Epistles 48–9) relates a similar case, and quotes Hartman and Gutterman. Mr. Lemon's case has been already referred to.

3. *Uterine hydatids.*—Of the nature of these productions, and their necessary connection or otherwise with conception, there exists, as in the case of fleshy moles, a complete want of accordance in the opinions of authors. Some maintain that they are not necessarily the result of conception, while others as strongly, and, as it appears to us, with much greater reason and truth, consider them as the product of disease attacking the ovum. Without entering into lengthened details on this subject, it appears proper to quote a few of the most respectable opinions on each side of this question before stating the result of our own experience on the subject. Dr. C. M. Clarke (Observations on the Diseases of Females, part ii. p. 115) thus expresses himself:—"It is probable that the existence of pregnancy is not necessary for the production of this disease. It has been believed to exist independently of this state; and perhaps a morbid condition of organized lymph may have the power of originating this disease under certain circumstances, but what these circumstances are is not known." Gardien's opinion is that "hydatids may be met with in girls as well as women; however, although they are independent of sexual intercourse, they are much more frequently met with in women who have borne children, and especially when they have arrived at the turn of life." (Traité complet, &c. t. i. p. 559.) Denman says:—"These have been supposed to proceed from coagula of blood, or portions of the placenta remaining in the uterus, and this opinion is generally true: but there is sometimes reason for thinking that they are an original production of the uterus independent of such accidental circumstances, and sometimes the precursors of organic disease in that part." (Introduction to Midwifery, fifth edition, p. 121.) Of these opinions we think we are justified in saying at least that there is so much of conjecture in them that they weigh very little in the determination of this point; and it is, moreover, to be observed that these writers admit elsewhere, as indeed do all who have written on the subject, that the existence of hydatids in utero is always accompanied by the ordinary symptoms of pregnancy. The weight of authority appears to us very decidedly in favour of the necessary connection between these substances and previous conception. Beck declares that he "can find no case on record where hydatids of the uterus have been formed *independent of sexual connection*." (Elem. Med. Jurisp. p. 102.) Baudelocque and Voigtel consider them merely as a variety of the mole, and as such the result of impregnation. (Locis citatis.) Desormeaux thus speaks of them: "It is superfluous to say that the development of these masses of hydatids is most frequently, if not always, the result of conception: at first it is impossible to distinguish this affection from pregnancy, *or, to speak more correctly, pregnancy exists* with all its phenomena, and it is impossible to discover when the degeneration into hydatids takes place." (Article "Œuf humain," Dict. de Méd. t. xv. p. 387.) Velpeau is perhaps even more decisive on the point: his words are, "the mole and hydatids of the uterus being but the products of conception degenerated, give rise to the same phenomena as true pregnancy." (Traité Elém. de l'Art des Accouch. t. i. p. 217.) We shall quote only one other authority, to which, however, we attach very considerable value. Madame Boivin has published a very ingenious and satisfactory pamphlet (Nouvelles Recherches sur l'origine, la nature, et le traitement de la Mole Vésiculaire ou Grossesse Hydatique, 1827) expressly on this subject, in which she brings forward a vast quantity of information connected with this affection, which she appears to have studied with unusual attention; and the result of her observations she announces to be that hydatids in the uterus are in all cases the result of conception. (Vide pp. 15, 24, and 56, Op. cit.) She notices the fact that these formations are not attached immediately to the internal surface of the uterus, but are sur-

* "Aussi sont-ce les seules productions que l'on rencontre chez les filles, et chez les femmes vivans dans l'état de chastité." Mad. Boivin sur la Mole Vésiculaire, &c. p. 18.

† It has been already remarked that these are not unfrequently found without any part of a fœtus. This is noticed also by Voigtel in describing different species of moles. "In others," he observes, "from an originally imperfect development of the ovum, or an injury to the fœtus at its first formation, it appears either as a shapeless mass, or *the fœtus itself is completely destroyed*, and *only its membranes and the placenta* continue to grow for a time and get thickened and fleshy, or filled with fluid only, or form membranous, fibrous masses, or hydatids, or assume other unnatural appearances." Voigtel, Op. cit.

rounded by an investing membrane having all the characters of the *decidua vera;* and she maintains that the hydatids originate in the filamentous vessels which spring from the external surface of the transparent membranes of the ovum; in regard to both which points we coincide in her views, and have in our possession preparations showing both facts. Our own belief, then, is that uterine hydatids do not occur except after sexual intercourse, and as a consequence of impregnation. We never met or heard of a case in which their presence was not accompanied or preceded by the usual symptoms of pregnancy; (such also was the experience of Dr. Gooch. See Account of the Diseases of Women, &c. p. 242–3;) and in every instance under our immediate observation, the women supposed themselves with child, and when the contents of the uterus were expelled, there was found either a blighted fœtus or some other part of the ovum.

It may not be amiss to notice here an argument from analogy which has been brought forward against this view of the question, viz. that hydatids being formed in other situations, as the brain, &c., why may they not occur in the uterus also, independently of any such circumstance as intercourse or conception? To this we would reply, first, that the hydatids produced in the situations alluded to differ, *toto cœlo*, in their characters from those of the uterus; and, secondly, that whenever hydatids are formed, it is always in connection with serous membranes, which do not exist in the uterus until the ovum is deposited there, whose membranes are essentially serous. Still it must be confessed that our knowledge on this point is by no means sufficiently precise, nor our collection of facts sufficiently extended, to warrant us in pronouncing positively on the question, or asserting decidedly, in a case of suspicion, that a woman was pregnant merely because she discharged hydatids from the uterus, except we could detect along with them some constituent part of the ovum, or in an examination after death find in the ovary the true corpus luteum, which ought to put an end to all doubt. It would be presumptuous and absurd to maintain that, because we had always found them in connection with one particular cause, there might not be some other also capable of producing them; and as there may be a doubt, we must let the accused have the benefit of that doubt. Again, in giving an opinion we should be prepared to make allowance for such a case as this: a woman loses her husband by death or departure, when she is, perhaps, in the third or fourth month of pregnancy; shortly afterwards she miscarries, and the placenta or some other portion of the ovum is retained, and gives rise to the production of hydatids. This new product may be retained for many months,* and being then expelled, might very unjustly excite suspicion against a perfectly chaste person: for, although the result of impregnation in such a case, they might obviously be no proof of a pregnancy occurring subsequently to the absence of the husband.

3. *Membranes expelled in dysmenorrhœa.*— The circumstances attending dysmenorrhœa have sometimes given rise to a suspicion of pregnancy and early abortion, because the female may have pains resembling those of labour, accompanied by red discharge, and followed by the expulsion of a substance somewhat resembling the decidua. But it only requires a little examination and inquiry into circumstances to detect the difference between these two products and the real nature of the case. In the first place, we learn that such occurrences are habitual with the person at every menstrual period; the symptoms of pregnancy have not been observed; nor does the state of the breasts correspond to the existence of that condition. Again, the substance expelled in such cases will be found deficient in several of the characters of the true decidua: it is thin, flimsy, and very unsubstantial in its texture, and has not the vascularity, nor the foramina for the reception of the nutrient vessels from the uterus, which are so distinctly observable in the decidua vera; and lastly, the most accurate examination will not discover within it any of the transparent membranes of the ovum. We cannot more appropriately close these observations on this membrane than by quoting the opinion of Denman, who, of all the moderns, has best described it. "As the first cases in which this membrane was discharged were those of married women, a doubt arose in my mind whether it was not really a consequence of early conception: but I have lately had the most undoubted proofs that it is sometimes discharged by unmarried women, and may be formed previous to and without connubial communication; and that the uterus has occasionally or constantly, in some women, the property of forming it at or in the interval between the periods of the menstrual discharges. It seems particularly necessary to establish this fact, as the appearance of this membrane has more than once given rise to erroneous opinions and unjust aspersions. Nor is this the only circumstance in which some women, at each period of menstruation, have symptoms like those which accompany pregnancy or parturition." (Introduction to Midwifery, pp. 161–2.)

Accidental Circumstances. — Under this head it is intended merely to notice certain peculiarities sometimes observable in pregnant women, which, although generally deserving but little attention in such an investigation, may still be remembered with advantage on account of the constancy with which they occur in particular individuals, and the assistance which they may consequently afford in confirming or modifying our opinion. Such is, for instance, the alteration so often observed to take place in the features and expression of the face, which has been made a subject of remark since the days of Hippocrates, who mentions it. The features of the face in general become sharper, especially the nose, which seems as if it were lengthened, and the mouth appears larger; the eyes are sunk, and often surrounded with a brownish or livid areola, and assume a languid expression. A marked change in the temper is very commonly observed also, so that a woman who was under ordinary

* In Madame Boivin's work, p. 74, there is a table showing the number of months which intervened in thirty-two cases between the commencement of pregnancy and the expulsion of the hydatids. Some interesting cases are detailed by Nanche in a well-written article on this subject. See Maladies propres aux Femmes, partie i. p. 182.

circumstances extremely mild and sweet-tempered, becomes, when pregnant, irritable and capricious. Strange appetites and antipathies are well known as frequent attendants on pregnancy in many persons, some of whom will long to eat unusual and even revolting articles, while others, immediately after conception, are seized with an unconquerable aversion to species of food which were previously particularly agreeable to them. We have seen several well-marked instances of this, and in particular one, in the case of a lady who assured us that she always knew when she was with child by feeling a violent antipathy to wine* and tea, which at other times she took with pleasure. We had an opportunity of observing the accuracy of this indication in three successive pregnancies of the lady alluded to. (See Gardien, tom. i. p. 485. Burns's Principles of Midwifery, p. 231. Denman, p. 232.) The occurrence of pains in the teeth, face, and other situations, are with some the invariable accompaniments of pregnancy. In some women the same condition develops very singular idiosyncrasies, such as the occurrence of dark blotches over the face and other parts of the skin, an instance of which is at present exhibited in a patient under the writer's care. Lecat relates the case of a woman whose face in three successive pregnancies became quite black. (See other instances by Gardien, loc. cit.) Camper observed the same circumstance. The occurrence of salivation in consequence of pregnancy has been already noticed. Some women always have varicose veins during gestation, who are not subject to such an affection at any other time. Mr. Ashwell mentions that in some individuals frightful dreams have been found a very good diagnostic sign; and he informs us that Dr. Haighton used to relate the case of a lady under Dr. Lowder's care, who was compelled to hire a nurse to awake her when her countenance became very much discomposed. (Treatise on Parturition, &c. p. 171.) A very curious case is recorded by Dr. Benneewitz in Osann's Clinical Report for 1823, of a young woman who in three successive pregnancies was affected with diabetes mellitus which completely ceased after delivery, but always returned when she again conceived. (Edinburgh Med. and Surg. Journ. vol. xxx. p. 217.) In first pregnancies we can gain little or no information from such accidental peculiarities, but their constant occurrence in successive instances ought to give them value in our eyes; the degree of value, however, must depend altogether on the distinctness with which we can ascertain their existence, or the reliance which we can place on the sincerity of those who report them to us. (See Mahon, tom. i. p. 162.)

The Blood, Urine, and Pulse.—It is very generally asserted that the blood of pregnant women *always* presents the buffy coat and other characters of inflammation, (see Blackhall on Dropsies, p. 279–80. Scudamore on the Blood, p. 148,) and this change in that fluid is even noticed by authors as one among the rational evidences of pregnancy. (Gardien, vol. i. p. 487.) The very general belief in this as a fact established, has probably arisen from the circumstance that pregnant women are seldom bled except when labouring under some form of inflammatory disease; but experience has fully taught us that no reliance whatever can be placed on the condition of the blood as an evidence of pregnancy. It is quite obvious that a woman exhibiting many of the symptoms of pregnancy, and yet not with child, may have her system under the influence of inflammatory action sufficient to cause the appearance of the blood frequently noticed in pregnancy; and on the other hand the blood of pregnant women will be very often found not presenting the characters supposed to be peculiar to it. This we have seen proved in several instances, and perfectly recollect the first case which particularly arrested our attention on this point; it was that of a very fat and robust woman who was seized with puerperal convulsions, and her blood exhibited not the least trace of inflammatory character. We have observed the same absence of such an appearance in blood drawn in the earlier periods of gestation to prevent abortion; and within the last few days we witnessed a very satisfactory instance of the same kind in the case of a lady in the ninth month of pregnancy, whom we judged it expedient to bleed for a very distressing cough accompanied with pain in the chest and great irritation of the bladder; the abstraction of blood gave her the most immediate and decided relief, but it appeared in every respect perfectly natural and healthy.

A peculiarity in the urine of pregnant women has long been a matter of popular belief; and Savonarola, who wrote in 1486, gives a minute detail of the changes which that secretion undergoes in the different periods of pregnancy: up to about the sixth month, according to this writer, "the urine is clear, and of a pale citrine colour, with a cloud on its surface; and about the middle of the fluid, a deposit like carded wool; but as pregnancy advances towards its close, the urine becomes redder and turbid when stirred." This condition of the urine Foderé thinks entitled to consideration, having, as he says, "verified the accuracy of the observation." (Méd. Légale, tom. i. p. 435.) Still more recently M. Nanche has brought this subject before the profession. (See the Lancette Française; also the Lancet, No. 417, p. 765.) He speaks of it as a discovery of his own, and does not appear to be aware of the observations previously made by others: his words are: "By allowing the urine of pregnant women or of nurses to stand for some time, in thirty or forty hours a deposit takes place of white, flaky, pulverulent, grumous matter, *being the caseum or peculiar principle of milk formed in the breasts during gestation.* The precipitation is more readily procured by adding a few drops of alcohol to the urine." To this observation he subjoins a very strong case, in which he ventured to affirm the existence of pregnancy in a woman who was subsequently examined, both per vaginam and with the stethoscope, by several medical men, and pronounced not to be with child; but her delivery shortly afterwards evinced the accuracy of his previous diagnosis. The editor of the Lancet informs us in a note, that he had "applied the test in one case, and found it perfectly correct." We

* This particular aversion is expressly noticed by Hippocrates as a sign of pregnancy, "vinum odio habent cibos aversantur." De infecundis, cap. 6.

have ourselves tried it in several instances, and the result of our trials has been this; in some instances no opinion could be formed as to whether the peculiar deposit existed or not, on account of the deep colour and turbid condition of the urine; but in the cases in which the fluid was clear, and pregnancy existing, the peculiar deposit was observed in every instance; and we think its appearance would be best described by saying that it looks as if a little milk had been thrown into the urine, which having sunk through it, had partly reached the bottom, while a part remained suspended and floating through the lower part of the fluid, in the form of a whitish, semi-transparent, filmy cloud. And in some cases in which pregnancy was suspected, but did not exist, no such deposit was observed; but it is superfluous to say that there is such a host of accidental causes capable of altering the condition of the urine as ought to make us very cautious indeed how we ventured to attach credit to a symptom so equivocal.

We may apply the same observation to the state of the pulse, which has been made a subject of remark since the days of Galen. We shall only observe that in pregnant women the pulse is almost always stronger and more rapid than is natural to the individual at other times; but we cannot tell in a particular instance what may be the exciting cause of the increased action; we cannot even be sure that it is not natural to the person, and at all events we are certain that there are a thousand circumstances of disease or accident which may equally produce it.

[Although a difference has been found to exist between the urine of an impregnated and that of an unimpregnated, female, it has not generally been found distinctive. M. Donné, indeed, (*Gazette Médicale de Paris*, 29 Mai, 1841, and *Cours de Microscopie*, Paris, 1844,) affirms, that during pregnancy it contains less uric acid, and phosphate of lime, than in the natural state,—a difference which may be accounted for, on considering the elements that are necessary for the formation of the organs of the fœtus. The crystallization of the salts of the urine is thus so remarkably modified, that by simple inspection, without examining the females, he has, in more than thirty cases, recognised the state of pregnancy at different periods. Of late years, the urine of the pregnant female has been found to contain a peculiar substance, which, when it is allowed to stand, separates and forms a pellicle on the surface. To observe this, the urine must be allowed to stand from two to six days, when minute opaque bodies are observed to rise from the bottom to the surface of the fluid, where they gradually agglomerate, and form a continuous layer over the surface, which is so consistent, that it may be almost lifted off the urine by raising it by one of its edges. To this pellicle, the name *Kiestein*, or more properly *Kyestein* (from κυειν, 'to be pregnant') has been given. It is whitish, opalescent, slightly granular, and may be compared to the fatty substance, which swims on the surface of soups, after they have been allowed to cool. When examined by the microscope, it has the aspect of a gelatinous mass without determinate form: at times, cubical crystals are observed in it, but this appearance is only seen when it has stood for a long time, and may be esteemed foreign to it. The kiestein remains on the surface for several days; the urine then becomes turbid, and small opaque masses are detached from the kiestein and fall to the bottom of the fluid: the pellicle then soon becomes destroyed. Various experiments have been made on this matter by Nauche (*La Lancette Française*, and *Lond. Lancet*, cxvii. 675;) Eguisier, (*Ibid.* Février 21, 1829, and *L'Expérience*, 25 Juillet, 1839;) Dr. Golding Bird, (*Guy's Hospital Reports*, April, 1840;) Mr. Letheby, (*Lond. Med. Gaz*, Dec. 24, 1841;) Dr. Stark, (*Edinb. Med. and Surg. Journ.*, Jan. 1842;) Dr. E. K. Kane, of Philadelphia, (*Amer. Journ. of the Med. Sciences*, p. 37, Philad. 1842;) and, by Drs. McPheters and Perry, resident physicians at the Philadelphia Hospital, (*Amer. Med. Intelligencer*, March 15, 1841, p. 369.) They show, that when taken in conjunction with other phenomena, the appearance of the kiestein is certainly a great aid in the diagnosis of pregnancy. Mr. Letheby found unquestionable evidence of it in 48 out of 50 cases between the second and ninth months of utero-gestation, and was unable to account for its absence in the two exceptions. The result of Dr. Kane's observations, which the writer had an opportunity of examining from time to time, and for the accuracy of which he can vouch, is stated by Dr. Kane as follows: *First.* kiestein is not peculiar to pregnancy, but may occur whenever the lacteal elements are secreted without a free discharge from the mammæ. *Secondly.* Although it is sometimes obscurely developed, and occasionally simulated by other pellicles, it is generally distinguishable from all others. *Thirdly.* Where pregnancy is possible, the exhibition of a clearly-defined kiesteinic pellicle is one of the least equivocal proofs of that condition; and *fourthly*, when the pellicle is not found in the more advanced stages of supposed pregnancy, the probabilities, if the female be otherwise healthy, are as 20 to 1 (81 to 4) that the prognosis is incorrect. The writer has distinctly noticed, in some of the cases, the cheesy odour of kiesteinic urine described by Dr. Bird. (See, on all this subject, Hüter, Art. *Schwangerschaft. Geburtshülfich*, in *Encyclopäd. Wörterb. der Medicinisch. Wissensch.* xxx. 577, Berlin, 1843, and Prof. T. R. Beck, in *Amer. Journ. of the Med. Sciences*, Jan. 1843, p. 112.)]

Usual Conditions of the Female.—Before entering on the last division of our subject, which will treat of the post-mortem examination, it appears necessary to advert to certain conditions in which a female may become pregnant, and her case be thereby rendered more obscure; as when, for instance, conception takes place,—1. in early youth or advanced age; 2. during the existence of disease, especially of a kind calculated to prevent conception, or to render its occurrence very improbable; 3. without the woman being conscious of having incurred the risk; 4. under circumstances not likely to be followed by such a result, as where copulation was only partially accomplished, &c., &c.

1. *The age of the individual.*—This may be such as, judging from what we observe in the ordinary course of nature, would appear either to

preclude the idea of impregnation, or at least to render its occurrence extremely improbable. The limits of the generative faculty in women are generally those of the function of menstruation, but in some rare instances women have been known to conceive before the catamenia had begun to appear, (see cases referred to under the second section of this article, [also, the writer's *Human Physiology*, ii. 350, Philad. 1844,] and after their cessation.

Conception before the age of fourteen is very rare, but it appears that instances of it have occurred. Bruce mentions that in Abyssinia he has frequently seen mothers of eleven years of age; and Dunlop witnessed the same in Bengal. (Beck's Jurisprudence, page 82, note.) La Motte delivered a girl who had not completed her thirteenth year. (Traité d'Accouch. obs. xxiii. p. 52.) Instances of conception at nine and ten years of age are recorded by Jubert Schwrigius (see Smith, p. 493, note, and Ballard, note on Metzger, p. 485) and others, but they scarcely appear deserving of credit; yet we find Dr. Good expressing his assent to such relations, and quoting Haller (Vide Blumenbach, Bibl. i. p. 558) and Professor Schmidt (Act. Helvet. iv. 162. Eph. Nat. Cur. dec. iii. ann. ii. obs. 172) in support of them. (Study of Medicine, vol. v. p. 157.) The earliest instance of pregnancy known to the writer was that of a young lady who brought forth twins before she had completed her fifteenth year. Sir E. Home knew two instances, in one of which a girl of thirteen, and in the other a girl of twelve, gave birth to children. (Philosophical Transactions, 1819, p. 61.)

So also pregnancy very seldom occurs after fifty, especially in women who have not previously borne children; but instances have from time to time occurred at unusually late periods in women who had formerly conceived. In the statement sent to parliament by Bartholomew Mosse when endeavouring to procure a grant for the Dublin Lying-in Hospital, he mentions that eighty-four of the women delivered under his care were between the ages of forty-one and fifty-four; four of these were in their fifty-first year, and one in her fifty-fourth. (Case of Bartholomew Mosse presented to the House of Commons, 1755). The succession to an estate was disputed in France because the mother was fifty-eight years old when the child was born: the decision was in favour of the fact. (Mém. de l'Académie de Chirurgie, tom. vii. p. 27). Colomb adduces a similar case, and Knebel (V. pol. ger. ek. i. p. 161) two, one of fifty-two years, and the other of fifty-four. "In May, 1816, Mrs. Ashley, wife of John Ashley, grazier, of Firsby near Spilsby, at the age of fifty-four was delivered of two female children, which with the mother were likely to do well." (Edinburgh Annual Register, vol. ix. part 2, p. 508.)

While writing these observations, an eminent accoucheur of Dublin (Dr. Labatt) informed us that he some time since attended a lady who was married when forty years of age, and that after remaining barren for ten years, she conceived for the first time when she was past fifty, went to her full time, and after a difficult labour bore a living child.

Capuron (Médecine Légale, &c., p. 92–3, and 98) quotes several cases of child-bearing in advanced age, among which are the following:— Pliny records the case of Cornelia, of the family of the Scipios, who at the age of sixty bore a son who was named Volusius Saturninus. Marra, a physician of Venice, mentions that he treated a woman for dropsy who was really pregnant, and he was deceived by her age, which was sixty. La Motte tells of a woman who refused to marry until she was fifty-one, in order that she might escape child-bearing; but she was disappointed, and bore a child. Valescus de Tarenta mentions a woman who continued to menstruate beyond sixty, at which age she bore her last child: Capuron adds that it was generally believed in Paris that a woman in the Rue Harpe bore a daughter at the age of sixty-three, and nursed it.

The occurrence of such cases, however rare, should at least have the effect of making us extremely cautious in pronouncing against pregnancy, merely because the individual may have exceeded by ten or fifteen years the period of life after which the generative faculty ordinarily ceases to manifest itself; or because the woman may have lived for many years a married life without conceiving, and then show symptoms of pregnancy. A highly interesting case of this kind is, at the moment of writing this, under our care. A lady now in her forty-third year, who was married to her present husband twenty years ago, remained without any promise of offspring until within the last few months; but having missed her menstruation in September last, and finding her size increasing, the writer was requested to see her in January, when she exhibited evident symptoms of pregnancy: she has since under the writer's care been delivered of a healthy boy after a natural labour of about *four hours*. Dr. Gooch relates a case almost exactly similar, which occurred in "a woman of forty-two years of age, and who had been married twenty-two years without ever being pregnant," when she at length conceived, and brought forth a child at the full time.*

2. *Complication with Disease.*—Pregnancy not unfrequently takes place in diseased states of the system, which would, *à priori*, render its occurrence very improbable, and which, when it does occur under such circumstances, give rise to an unusual difficulty in recognising its existence. From this circumstance have from time to time arisen some very lamentable mistakes in practice. Thus women who have been long labouring under a general infirmity of health and with very irregular menstruation, or even a total suppression of that discharge, may conceive, and under such circumstances the phenomena of pregnancy are likely to be much obscured, or even their existence at all rendered very doubtful. Such a case is mentioned by Professor James of Philadelphia, in which a woman conceived after having had the menses suppressed for nearly two years before. (Hosack's Med. and Phil. Register, vol. iv. p. 422.) Diseases which increase the size of the abdomen, as they on the one hand often induce the supposi-

* Diseases of Women, p. 220. The following is inserted in the Scots Magazine for the year 1769, vol. xxxi. p. 279, under the head of "Births:" "May. At Doncarney in Ireland, in the 85th year of her age, the wife of one Rogers, a labouring man, of a boy!!!"

tion of pregnancy when it does not exist, so on the other hand they sometimes render its detection a matter of great embarrassment. Several instances have occurred in which women labouring under dropsy, even when the complaint was the result of serious organic disease, and had existed for a long time, have proved with child, and from the combination of circumstances thus produced great doubt and difficulty are likely to arise, especially when the woman is not herself aware of her condition, as happened to the wife of the king's council mentioned by Mauriceau, who was treated during seven months of her pregnancy for dropsy, and then brought forth a child. (Tom. i. p. 73.) In some instances very grievous errors have been committed. Mauriceau relates two cases of this kind, in one of which the woman had been nine years affected with dropsy in an extreme degree, but had during that time given birth to four children. (Maladies des Femmes grosses, tom. ii. obs. 70 and 249.) M. Chamsern had a patient who was tapped one hundred and sixty-nine times, and during the course of the disease she bore and suckled two children, though during each pregnancy it was found necessary to tap her three times.* Foderé mentions two women who, being pregnant, were tapped under the idea that they had dropsy; (Médecine Légale, tom. i. p. 463–4.) the uterus fortunately was not wounded; but in another case of distended bladder accompanying pregnancy and mistaken for dropsy, the practitioner tapped the patient; "death was the consequence, and on examination it appeared that the trochar had passed through both sides of the bladder, through the uterus, and even into the head of the child." (Lowder's MS. Lectures, quoted by Gooch, on Diseases of Females, p. 240 and note.) Capuron mentions that Marsa, a physician of Venice, treated a woman for dropsy, who was pregnant, being deceived by her age, which was sixty.† In a case which occurred to the writer, pregnancy remained a matter of the utmost doubt until the seventh month; the woman died two days after delivery, and the liver was found tuberculated, hard as cartilage, and diminished to about one-third of its natural size. "The bare possibility of such cases," says Gooch, "is a strong reason for never tapping a married woman without having the uterus previously examined by a person skilful in such examinations." Beck makes the following observations on this subject: "The most difficult case of concealed pregnancy that probably can occur, is when it is accompanied with ascites. The motion of the fœtus cannot be perceived; and it is added by Foderé, that the uterus does not take on its ordinary development. Yet many cases are on record where females with this disease on them have been delivered of healthy children. In suspected cases the practitioner should weigh the symptoms and ascertain whether they are all referable to the disease. His medicines should be mild, and patience exercised as to the event." (Elem. Jurisp. p. 81.)

Enlargement of the ovary is another disease which may either simulate pregnancy or coexist with it,‡ and the abdominal enlargement increasing may be mistaken for the progress of the disease; when both ovaries are affected, pregnancy is of course much more improbable, yet it has occurred. Morgagni declares that even in disease of both ovaries, if there remain healthy a portion containing one vesicle, the woman may conceive.§ A case very lately occurred in this city, in which a lady with ovarian enlargement at both sides, and of considerable size, became pregnant, and her true condition was not recognized until pregnancy was very far advanced, when the application of the stethoscope detected the pulsations of the fœtal heart. Under such circumstances a proper examination of the uterus per vaginam ought to enable us to detect the nature of the case. On the other hand, the existence of such a disease has repeatedly given rise to the suspicion of pregnancy. In the celebrated case of the Demoiselle Famin, published at Berlin and Paris by Valentin, in 1768, a charge of pregnancy and child-murder was erroneously instituted in consequence of an extreme case of ovarian dropsy.

The writer had once an opportunity of examining a very remarkable case, which presented a combination that could hardly fail to be attended with infinite doubt. A woman was received into the Cork-street Fever Hospital in 1828, with considerable enlargement of the abdomen. Her history, as far as it could be learned, was, that eight years before she had been in labour, which, after continuing for two days, suddenly ceased, and the child, as she expressed herself, rose up into her stomach: no delivery followed. After remaining in bad health for about two years, she again experienced the symptoms of pregnancy, and gave birth to a child, which did not survive; but the former child still remained in the cavity of the belly, and during its continuance there she bore three children, the last of whom lived. Ultimately a fistulous opening formed near the umbilicus, which was enlarged, and the original child removed; it was in a state of wonderful preservation, measured twenty-two inches in length, and had attached to it about two feet of the umbilical cord.‖ Some of the most formidable diseases of the uterus have been found not incompatible with conception, and even the completion of the full term of gestation. Thus, instances of the concurrence of polypus, uteri, and pregnancy have been several times witnessed;¶ and in some cases the placenta has been found attached to the polypus.** The writer has a preparation in which an early

¶ See Gardien, tom. i. p. 443,—Gooch, Diseases of Females, p. 290,—Dr. Beatty in Trans. Assoc. Coll. Phys. Ireland, vol. iv. p. 1. London Med. and Phys. Journal, vol. xxvi.

** See Glasgow Medical Journal, vol. i. p. 422. Bach. Mayor de Polypis, quoted by Cooper in the Surgical Dictionary, article *Polypus*.

ovum is thus connected. Levret,* Bach, Joerg, and Dr. Macfarlane have recorded cases in which the fœtus reached its full time under such circumstances. Even cancer and fungoid diseases of the uterus have been proved not to prevent the occurrence of pregnancy,† and a scirrhous cervix has been found an obstacle in the time of labour,‡ Gardien expressly states that numerous facts within his knowledge have proved to him that women may carry their children to the full time although labouring under cancer in the ulcerated state.§

Women have been impregnated although afflicted with complete external prolapse of the uterus. M. Guillemot has written a very interesting paper on this subject, in which he has collected from various sources nine cases of the kind, the first two of which are particularly remarkable as examples of gestation accomplished where the prolapse was complete. (Quoted from, 1. Archives de la Soc. d'Emulation. 2. Journal de Méd. et de Chirurgie for 1775.) In the third case impregnation occurred while the uterus was completely external.‖ Another of the cases happened in the practice of the great Harvey, who gives us the following account of the matter: "And now at this time it was large and dangling between her leggs. It grew at last bigger than a man's head, being then a hard tumour, and hanging downe to her knees did much pain her, so that she could not goe but upon all foure. I did suspect it to be a cancer of the wombe, and therefore did bethink my selfe of a ligature and cutting it off: but the following night an infant perfectly shaped, of a span long, was cast out of that tumour, but it was dead." (Anatomical Exercitations concerning the Generation of living Creaturcs, p. 494.)

We have thought it advisable thus to enter fully into the statement of such unusual conditions, lest a proposition on our part against the possibility of such occurrences should act unfavourably, either by closing our eyes against the evidence before us in extraordinary cases, or making us less careful in their examination from a pre-conviction that pregnancy could not under such circumstances exist.

3. *Conception without the knowledge of the woman.*—That a married woman, or any female who has indulged in sexual intercourse, may become pregnant without being aware of her condition, is a fact too notorious to require further obscrvation than the mere mention of it. the question which we propose to consider here is,—can a woman become pregnant in consequence of intercourse, of the occurrence of which she was not conscious, and so find herself with child without being aware of having incurred the risk? Improbable or even absurd as such a supposition may at first sight appear, the possibility of such an accident is established by too many facts testified by high authority, to permit incredulity on the subject. The belief that consent and pleasurable sensation on the part of the woman are conditions necessary to conception is now universally known to be without foundation in nature, and of course no longer influences legal decisions: formerly, however, it was otherwise, so that in case of rape, if pregnancy followed, it was presumed to prove consent, and it was so laid down by Dalton; (Dalton, c. 160. See also, 2 Just. 190,) but Lord Hale says that this opinion of Dalton seems to be no law. (1. H. H. 131. See also, MSS. Sum 334.) "That so absurd a notion as that conception evidenced consent should in modern times have obtained amongst any whose education and intellcct were superior to those of an old nurse, is indeed surprising; at this day, however, facts and theory concur to prove that the assentation of nature in this respect is no ways connected with volition of mind." (Burn's Justice, tit. Rape.) "It is a fact," says Capuron, "which experience has more than once confirmed, that a woman may become with child while in a state of hysteria, under the influence of narcotics, during asphyxia, drunkenness, or *deep sleep*, and consequently without being conscious of it, or sharing the enjoyment of the man who dishonours her;" and in proof he mentions having attended a young woman who was got with child while totally unconscious, being buried in a deep sleep produced by punch given her by her paramour. (See Méd. Lég. relat. aux Accouchemens, pp. 57, 84.) She became aware of her condition for the first time when she felt the sensation of motion in the fourth month. Foderé expresses a similar opinion, and quotes several instances in which the occurrence took place, one of which is particularly remarkable. (Médecine Légale, tom. i. pp. 497 et seq.) MM. Marc (Dict. de Méd. tom. xxi. p. 358–9,) and Raige Delorme (Dict. de Méd. tom. x. p. 465–6. See, also, Smith, Forens. Med. p. 401,) speak of such a fact as established by experience. Dr. Gooch says, "it is not necessary that the woman should be sensible at the time of impregnation," to which observation the following case is subjoined: "A maid at an inn, who was always thought to be virtuous, and bore a good character, began to enlarge in a way which excited suspicions of pregnancy; she solemnly declared that she never had connection with any man. At length she was delivered, and was afterwards brought before a magistrate to swear to the father; but she repeated her former declaration. Not long afterwards a postboy related the following circumstances: that one night he came late to this inn, put his horses into the stable, and went into the house; he found all gone to bed except this girl, who was lying asleep on the hearth-rug, and without waking her he contrived to gratify his desires." "This shows," he adds

A most remarkable case of this kind has been recorded by M. Neyzonis, in which the woman died undelivered; the parietes of the uterus were found carcinomatous, and three inches thick near the fundus. Dict. des Sciences Méd. tom. iv. p 237.

§ Traité d'Accouch. vol. i. p. 430.—See Raige Delorme, Dict. de Méd. tom. x. p. 464.

‖ From Chopart, Malad. des Voies Urinaires, vol. i. p. 389, note. The circumstances of this case were very remarkable. The woman was married at twenty years of age, and during twenty-one years "son mari fit des tentatives infructueuses pour la rendre mère; enfin au bout de ce tems-là, il parvint à dilater l'orifice de la matrice qui étoit hors des grandes lèvres, et consomma l'œuvre de la génération." The account of the labour and delivery, &c. are full of interest.

"that impregnation may take place without the knowledge of the female." (Compendium of Midwifery, p. 81–2.)

In reference to this question Beck remarks, "In females habituated to sexual connection, or where sleep is unnaturally produced, there is no doubt of its occurring; whereas in the opposite cases the probability is greatly lessened;" (Elem. Med. Jurisp. p. 92); and in a note on this passage he quotes the following case: "A pregnant female in her last moments solemnly declared that to her knowledge she never had connection, but that a person in the family some time previous had given her some wine to drink, after which she fell into a profound sleep. She was not, however, conscious of any thing having occurred during that state, but mentioned the circumstance as probably explaining her situation." (Mierius in Brendel, p. 99.) A case very much resembling that related by Dr. Gooch has just been mentioned to the writer by Mr. Cusack, which occurred under his own observation. A servant woman at an hotel in Neaugh proved pregnant, and solemnly declared that she was not conscious of having had intercourse with any man. Suspicion, however, fell upon an hostler in the establishment, who subsequently acknowledged that he believed he was the father of the child; that having found the woman in a deep sleep from fatigue, caused by long-continued exertion and being kept out of bed two or three nights in succession, he had connection with her, and, as he believed, totally without her knowledge, as she did not evince the slightest consciousness of the act at the time, or recollection of its occurrence afterwards; the parties were married with mutual consent.

We once attended a patient who even in her dying hour protested in the most solemn manner that she was not conscious of sexual intercourse; and when we recollect that delivery has occurred during sleep, we cannot doubt but that coition, which is so much less likely to disturb, may be consummated during sleep with a female accustomed to sexual indulgence without her being afterwards aware of it. That such an event must be of very rare occurrence is certain, but we cannot deny its possibility, and therefore we are furnished with an additional reason for refusing implicit assent to the statements of females, who, as they will in ordinary cases of illegitimate pregnancy deny the possibility of their condition with the most unparalleled effrontery and the most solemn and imposing protestations, so should we, on the other hand, recollect that impregnation may possibly have been effected without their knowledge; so that, however highly we may esteem their general credibility in other matters, in this they may either try to deceive us or be themselves deceived; we must therefore form our opinion not by what we hear, but by what we can see and feel.

[Yet the cases adduced of conception without consciousness of intercourse on the part of the female are few, and by no means overwhelming. If, indeed, it be requisite, that through venereal excitement, the Fallopian tubes must embrace the ovary, in order that the sperm may reach the ovary and impregnate an ovum, it is difficult to comprehend how conception can take place without some *feeling* on the part of the female.]

The following case is quoted by Bruhier, Foderé, (Médecine Légale, tom. i. p. 500–1,) and others, (Louis, Lettre sur la certitude des Signes de la Mort,) from the Causes Célèbres, to show the possibility of conception during a state of complete asphyxia or apparent death. "A young friar being on a journey, arrived at a house where they were about to bury a young girl, whom they believed to be dead. He proposed to pass the night in the chamber with the coffin and watch the body. In the course of the night, while examining the body, his passions were so excited by the beauty still remaining, that he determined on satisfying them even under such circumstances. He departed early next morning, and in the course of the day the apparently dead revived, proved to be pregnant, and at the end of nine months brought forth a child, to the great amazement of her friends as well as her own. The friar returned to the place about this time, confessed himself the father of the child, and married the mother, having procured absolution from his vows, which he had taken against his will."

4. *Presence or absence of the hymen.*—It seems almost unnecessary to remark that the presence of the hymen, however perfect its condition, cannot be assumed or depended on as a conclusive proof against the previous occurrence of impregnation, for although it certainly ought to be considered as strong presumptive evidence in favour of virginity, so many cases have been witnessed and put on record by authors worthy of credit, in which that membrane has been found coexisting, not alone with pregnancy, but even with labour, that the fact no longer remains a matter of doubt, Meckel (Anatomie Descriptive, &c. vol. iii. p. 735,) remarks that "the hymen cannot be considered a certain physical sign of virginity, because, on the one hand, it has been often found entire not only in women who had frequently indulged in sexual intercourse,* but even in some who had brought forth fœtuses advanced even so far as the seventh month."† The writer was once consulted by a young person whom he found to be pregnant, but whose hymen was as perfect as it had probably ever been; but the opening through it was such as to admit the finger to pass without difficulty, and the girl acknowledged that she had on more than one or two occasions enjoyed the embraces of a very young gentleman, on whose youth it appeared she had relied for immunity from the usual consequences.‡ The existence of the hymen at the time of labour has been detailed by Ambrose Paré, Willis, Ruysch, Nœgele, Baudelocque, (Art des Accouchement, vol. i. ch. 3,) Mauriceau,§ and many others: the cases related by the last two are particularly remarkable. § Maladies des Femmes Grosses, tom. ii. obs. 489, p. 405, and obs. 583.

Davis* also refers to more than one case of this kind. Velpeau (Traité d'Accouch. tom. i. pp. 63–4,) mentions having met with the hymen entire in the body of a woman of forty, "who had long cohabited with her husband, but without having children." The writer once witnessed a similar case in an old lady of 80, who had been married and lived thirty years with her husband without having children: when visited by the writer, she had been some years a widow, and examination of the parts became necessary in consequence of an affection of the urethra; the hymen would not permit the passage of the point of the little finger without difficulty.

On the other hand we believe it is a matter of universal agreement, that there are many causes besides sexual intercourse capable of destroying this membrane, which there is also good reason for believing may in some cases have been originally defective from imperfect conformation of the part. (See Meckel, loc. cit.) In another part of this article the imperforate hymen has been noticed, and its effect in inducing suspicion of pregnancy by preventing the discharge of the catamenia. And it is scarcely necessary to observe here, that in such a case the mere discovery of the obstacle would be proof positive against the condition suspected. Among the Jews a discharge of blood as the consequence of the laceration of the hymen in primis nuptiis, was considered so unequivocally the test of virginity, that it was made a subject of legislation, and the woman to whom this did not happen was liable to be stoned to death. (Deuteronomy, chap. xxii.) Gardien mentions that the Jewish custom prevails to a certain extent at the present day amongst the Bedouin Arabs; and Mahon, on the authority of Chappe, speaks of a similar custom as at present existing in Siberia and in certain parts of Russia. (Médecine Légale, tom. i. p. 123.) It has been remarked by Foderé, Mahon, and others, that the state of the hymen may vary much in the same individual at different times and under different circumstances; and the latter mentions a case where a man not finding it existing in his bride took great offence, but afterwards finding a totally different condition of the part, recognised his error and was satisfied. (Loc. cit. p. 121.) Marc has recorded a very remarkable case illustrative of this, and, as he says, "showing that, when the hymen is of the semilunar form, it may disappear for a time, and return again." (See the statement of Buffon, as quoted by Mahon, tom. i. p. 127–9.) "A young girl, not 13 years of age, formed an illicit intercourse with a man, in consequence of which she was severely affected with syphilis, for the cure of which she was brought to the hospital of La Pitié: on examination by Dr. Serres and others, there was found extreme dilatation of the vagina, injury of the external genitals, and total absence of the hymen: she was cured, and then they were greatly astonished to find all the physical marks of virginity existing, especially a well-marked semilunar hymen. MM. le Docteur Fournier, Pescay, and Marc were appointed by the Medical Society of Emulation to examine the fact." (Dict. de Méd. Art. *Violation*, by Marc. vol. xxi. pp. 353–4.)

As a suitable conclusion to this section we shall notice a very remarkable case recorded by Nysten, forcibly illustrating the necessity of attending to these unusual conditions, as not being incompatible with pregnancy, which in the case alluded to occurred in combination with several such. In this instance, 1. the pregnancy was ovarian; 2. the girl was only thirteen years old; 3. she had never menstruated; 4. the hymen was perfect; 5. the vagina so contracted that it would scarcely admit the tip of the finger; 6. the organs of generation and the breasts like those of childhood." (Journal de Médecine par MM. Corvisart et Leroux, brumaire, an 11. p. 144, et seq.)

Examination of the Uterus and its appendages after death. — It is unnecessary to repeat here what has been already particularly set forth with regard to the state of enlargement in which the uterus must be when containing the product of conception. In relation to our present subject, the first and most obvious fact to be noticed is, that when an examination is made after death, and the uterus found of its naturally diminutive size, it is proof positive against the present existence of pregnancy. If, on the other hand, we find the organ enlarged, and its condition apparently corresponding to the period of pregnancy supposed to exist, nothing but a careful examination of its contents, or other cause of enlargement, can determine the question at issue. We will here only observe that nothing less than the distinct and unequivocal detection of the ovum or some of its component structures ought to satisfy our minds, or justify us in giving an opinion in the affirmative. (See section on *Substances expelled from the uterus.*)

Another condition of the uterus which may present itself, is that in which it is found enlarged but empty, exhibiting, however, several of the changes which accompany gestation: these, however, upon examination will only afford evidence sufficient to convince us that the organ has recently been distended by something contained within it, and which had been attached to its internal surface by a vascular connection: the substance expelled may or may not have been the product of conception; and the most careful examination of the appearances remaining, or of the structural changes effected, will not enable us to pronounce safely on the precise nature of the cause which had produced them. Thus, for instance, in a case where hydatids have been expelled, we could not determine by examination of the uterus alone, whether the conditions there observable were the result of true pregnancy and the expulsion of a fœtus or ovum, or whether they might not have been produced by some other cause unconnected with conception: we may not, in fact, be able to tell without further investigation whether the woman have recently conceived or not, a question which it may be occasionally of paramount importance to be able to answer: we must therefore turn our attention in another direction, and seek for proof of impregnation in the appendages, particularly in that part of them which is more especially the seat of conception.

* Principles of Obstetric Medicine, p. 104. See also Gooch's Compendium of Midwifery, p. 81, and Paris and Fonblanque, vol. i. p. 203. Several similar cases are mentioned in Merriman's Synopsis of difficult parturition, see pp. 58 and 228, 4th ed. See also Smellie, Collect. xxxi. case 26, p. 62.

This leads us at once to investigate the value of that peculiar change in the ovary, by which, after the vivification of the germ, there is produced a new structure, to which has been applied the name of *corpus glandulosum*, or more generally, *corpus luteum*, — a production the presence of which is by some considered incontrovertible evidence of impregnation. Others, however, with equal confidence discredit the value of its presence, and assert that its existence may be owing to causes altogether accidental and independent of sexual intercourse, and that consequently it cannot be taken as certain evidence of conception. It becomes, therefore, a matter of vital moment to examine the truth of such assertions, and to determine, if we can, how far they coincide with or depart from absolute matter of fact, which alone can be the measure of their correctness, and consequently of their value. In order to do this, the first thing which appears to us essentially necessary is, that we should have a clear idea of what a true corpus luteum is, and of what is not a corpus luteum.

If this inquiry should appear to any one superfluous, it is only necessary to turn to the generality of books in which it is mentioned, and then compare the descriptions to be found there with the object as it exists in nature, and we must be convinced how faint is the resemblance between the portrait and the original. We are inclined to think that the naming of this substance has given rise to much of the error which exists and is propagated on the subject, the colour being assumed as the only characteristic necessary to constitute the corpus luteum. Whenever small spots, or even points, of a yellow hue are met with in the ovaries, they are supposed to be true corpora lutea. We recollect distinctly the first time our attention was drawn to the subject was at a demonstration of the structure of the ovaries, when two spots, each not larger than a grain of mustard-seed, and of a yellow colour, were exhibited as specimens of corpora lutea, and as proving that the woman had, during her life, borne two children.

A trial took place some years ago in Edinburgh, which, while it evinced the necessity for a correct knowledge of this subject, which might occasionally arise even under circumstances not apparently connected with its existence, proved but too plainly how little was known about it. A prosecution was instituted against four medical students for exhuming the body of a lady in Glasgow. The body was so disfigured that it could not be identified: the ovaries were, however, examined, and it was reported that there was in one of them a perfect corpus luteum, which would be sufficient to prove that the remains were not those of the lady in question, who was a virgin, and advanced in life. On the trial there was a complete contradiction between the medical witnesses, one-half of whom affirmed the appearance in the ovary to be a true corpus luteum, while the others maintained that it was not; so that no satisfactory inference could be drawn from the fact. The body was afterwards identified by a dentist producing a cast which he had taken of the gums.

If we examine the ovaries of a woman who has recently conceived, we observe that the one which has supplied the germ differs in several remarkable particulars from its fellow of the opposite side: it strikes the eye at once as being larger and more vascular; to the touch it feels fuller and softer: we perceive further, that this increase of size of the one is not so much the result of an increased development of the whole substance or body of the organ, as of the addition to it at one part, of a tumour projecting more or less from its natural outline, as we find in the eye, where the circumference of the cornea projects from the outline of the globe, the segment of a smaller circle being superimposed on that of a greater.

When we examine this protuberance, we find that the increased vascularity of the organ is nearly confined to its limits, and very frequently we perceive that the colour of this part is completely different from the rest of the substance, giving the notion of deep or dull yellow seen through a slightly reddish medium; and lastly, we observe on some part of the external covering of this prominent part a distinct cicatrix, or appearance as of a rent imperfectly united.*

We should observe here that these external changes by which we recognise the existence of the corpus luteum within, are to be seen most remarkably in some of the lower animals. In cows it is not unusual to see the corpus luteum projecting almost like a parasitic tumour from the side or cud of the ovary; the same may be said of the sheep, and of animals which naturally have the Graafian vesicles very prominent, as the hedgehog or common sow, in which they absolutely project from the surface: in this animal the ovaries after conception appear literally like bunches of round berries, from the great prominence of the numerous corpora lutea.

Having satisfied ourselves of the presence of the external characters, we proceed to examine the internal structure; in order to do which we should make a section of the ovary, carrying the knife through the centre of the prominent part so as to divide the ovary into two longitudinal sections, by which we expose the corpus luteum presenting the following characteristic appearances.

In *form* and *size* it is almost always an oval, with its longer axis varying from four to five eighths of an inch, and the shorter from three to four eighths; its thickness is generally less than its breadth.†

Its texture is obviously and strikingly glandular, resembling a section of the human kidney; (see De Graaf, p. 177); or, as some one has said, it is like a miniature of the particular sections of the brain called by anatomists *centrum ovale*. William Hunter describes it as "tender and friable, like glandular flesh." (Anatomy of the Gravid Uterus, p. 14.)

---

* In the case examined by Sir E. Home and Mr. Clift, where the woman died eight days after impregnation was supposed to have taken place, "the right ovarium had a small torn orifice upon the most prominent part of its external surface. We slit it open in a longitudinal direction, in a line close to the edge of this orifice; the orifice was found to lead to a cavity filled up with coagulated blood, and surrounded by a yellowish organized substance." Philos. Trans. 1817, p. 254.

† "Pene hemisphericum, avellanæ mole." *Haller.* — "Longum quatuor lineas, latum tertias lineas, crassum duas lineas." *Rœderer.*

It is very vascular, small vessels being very frequently visible without any preparation; but if fine-coloured injections have been previously thrown into one of the branches of the spermatic arteries going to the ovary, the vessels of the corpus luteum will be filled with the colouring matter, and are to be seen very distinctly running from its circumference towards its centre.

Its colour is, as its name implies, a dull yellow, very similar to that of the buffy coat of the blood; exhibiting generally, when recently exposed, a slightly reddish tinge, "*ex flavo rubens*," Haller.

Its centre exhibits either a cavity or a radiated white cicatrix according to the period at which the examination is made: if within the first three or four months after conception, we shall frequently find the cavity still existing, and of such a size as to be capable of containing a grain of wheat;* this cavity is surrounded by a strong white cyst, and as gestation proceeds, the opposite parts of this cyst approximate and at length close together, by which the cavity is completely obliterated, and in its place there remains a white cicatrix, whose form is best expressed by calling it radiated. Of this latter appearance it ought to be observed here that it is visible as long as any distinct trace of the corpus luteum remains, and forms an essential character, distinguishing this body from every other that might be confounded with it.

After the period of gestation has been completed, or the contents of the uterus prematurely expelled, so that gestation ceases, the corpus luteum soon begins to exhibit a very decided alteration in all its characters, until at length it is no longer to be found in the ovary. The exact period of its total disappearance we are unable to state; but we have found it distinctly visible so late as at the end of five months after delivery at the full time, but not beyond this period; and the corpus luteum of a preceding conception is never to be found along with that of a more recent, when gestation has arrived at its full term; but in cases of miscarriage repeated at short intervals, it may. At the time of delivery the corpus luteum is neither so large nor so vascular as at the earlier periods of pregnancy, except the woman should happen at the time of her death to be labouring under inflammation of the uterine system, in which case the corpus luteum partakes of the turgescence of the other parts, and very remarkably of their increased vascularity.

In the ovary of a woman who died of inflammation of the womb a few days after delivery, and which is preserved in the writer's museum, the white central cicatrix is very distinct, and externally the ovary continues to exhibit the superficial cicatrix and the alteration of form produced by the projection of the part containing the corpus luteum. In another preparation, which shows the appearance of the corpus luteum in a woman who died of pneumonia exactly five weeks after delivery at the full time, it is diminished in size to about one-half of its original dimensions, is closer in its texture, and its colour was becoming indistinct in numerous points, so that it appeared paler, but the radiated central cicatrix is quite distinct; its vascularity also was diminished, as fine injection could not be got to pass into it: the external surface of the ovary exhibits the greater size and prominence of one part, and the fissure on it is still well marked; and it is particularly deserving of remark here that there is *only one cicatrix* observable on each ovary, although the woman from whom they were taken had borne six children.

In another specimen in our collection, taken from the body of a woman who died in the twelfth week after delivery, the external prominence was greatly diminished, but was still sufficiently obvious to indicate the exact situation of the corpus luteum, as was also the superficial cicatrix; the corpus luteum itself had lost much of its colour, and what remained became, on immersion into spirits, of a light grey shade; the texture of its substance was more condensed, and resembled that of a cut apple; and its dimensions, especially in breadth, are reduced to about one-third or rather less, but the central radiated cicatrix is still distinctly observable.

Lastly, in the case of a young woman who died *five months* after giving birth to her first child, the ovary retained very little of its increased size or altered form; the prominence was hardly to be recognised; but the external cicatrix was perfectly obvious. When opened, the corpus luteum exhibited its peculiar colour only in one very small spot, rather larger than a mustard-seed, within which is still observable the central radiated cicatrix; the yellow colour completely disappeared when immersed in perfectly pure rectified spirit diluted with water.† Beyond this period we have never detected the existence of the corpus luteum: the vulgar notion, however, is that it is a permanent structure, and that consequently we have only to examine the ovaries after death to enable us to tell not only whether a woman has borne children, but the exact number of her offspring, from the number of corpora lutea existing in the ovary. This is quite an error, and probably arose from a misconception of the meaning of such an expression as that of Haller, when he says—"Numerum credo eundem esse, qui est fœtuum," (Elem. Physiologiæ, vol. viii. p. 36); or, as in another place, "Numerus corporum luteorum est in ratione fœtuum." (Op. Min. vol. ii. p. 457.) By this expression, however, he only meant that their number was the same as that of the fœtuses lodged in utero in one gestation, which indeed we find expressly stated by De Graaf, whose words are—"Deteguntur, unus aut plures, prout animal ex illo congressu unum aut plures fœtus in lucem edet." (De Organis Mulierum Generat. &c. p. 178.) Hence, when there is only one fœtus, there is only one corpus luteum. In cases of twins or three children, there will be a corresponding number of these bodies in the ovary or ovaries, for they may be all formed in one ovary only, or some in each. This suggests a circumstance of very great importance connected with the number of these bodies which may be found; which is, that occasionally a corpus luteum may be discovered with-

* "Cavea dimidiam lineam lata, non profunda," *Haller*. We once met with this central cavity in the ovary of a cow recently impregnated, large enough to receive the end of the little finger.

† This does not happen when the corpus luteum, taken during gestation, or just at the time of delivery, is placed in contact with the same fluid.

out a fœtus, or a greater number of them than there are fœtuses produced at the time. Thus, in one instance we found two corpora lutea in the ovary of a woman who killed herself by medicine taken to produce abortion. She was reported to have expelled but one ovum. Haller notices this occasional occurrence, and explains it thus; "Si unquam absque fœtu corpus luteum in ovaria repertum est, quod est rarissimum, credibile est eum fœtum abortu perditum aut alio modo destructum disparuisse." (Elem. Physiologiæ, vol. viii. p. 36.) We have had several opportunities of verifying this observation, and, amongst other instances, we once found ten corpora lutea in the ovaries of a sow, but only nine fœtuses in the uterus; but at length, after a very diligent search, we discovered in one of the cornea the remains of another fœtus which had been blighted and was in a state of partial decomposition. Haighton also observed this occurrence, but adds that "the uterus in these cases has borne the marks of an early and recent abortion," (Philosophical Transactions for 1797, p. 166); and Cruikshank, as mentioned in another place, speaks of the corpus luteum as a certain mark of conception, "whether the embryo is visible or not." (Philosophical Transactions. 1797, p. 200.) We may remark that from such facts follows of necessity this circumscription of the conclusion to be drawn from what we may observe in the ovaries,—viz. that the presence of a corpus luteum does not prove that a woman has *borne a child*, although it would be a decided proof that she had been impregnated and had conceived; because it is quite obvious that the ovum, after its vivification, may be, from a great variety of causes, blighted and destroyed long before the fœtus has acquired any distinct form. But the converse will not hold good. We believe no one ever found a fœtus in utero without a corpus luteum in the ovary, and that the truth of Haller's corollary, "nullus unquam conceptus est absque corpore luteo," (Opera Minora, vol. ii. p. 458,) remains undisputed.

Considering the results constantly presented to us by examination, we feel utterly at a loss to imagine what could have induced the following assertion of Sir E. Home: "The remains of the corpus luteum at nine months *after impregnation of the ovum*, are so indistinct as hardly to be recognised; but in the opposite ovarium there is commonly a corpus luteum far advanced, forming another ovum; and it will be found that all the preparations of corpora lutea taken from the ovaria of women who die in childbed, actually belong to this new ovum not yet completely formed." (Philosophical Transactions, 1819, p. 63.) Now, our experience convinces us of the contrary of every statement here made, and we think that one question will be sufficient of itself to show their inaccuracy: premising that we deny altogether the statement that there is "commonly" found a second corpus luteum, we ask, if this corpus luteum always found in the ovaria of women who die in childbed belongs to the ovum not yet completely formed, how does it happen that we always find on its surface the cicatrix through which the ovum has already escaped?

A similar and equally erroneous idea obtains very generally with regard to the cicatrices on the surface of the ovaries, which have been already noticed as marking the situation of the corpus luteum. These are supposed by many to be permanent and ineffaceable, and of course certain indications of the number of children borne by the woman during her life, or of the number of times she had conceived. But such is not the case; the ovaries of women who have borne several children will sometimes be found exhibiting only one or two of these rents or marks on the surface, a very distinct instance of which has been already noticed; the woman in this case having given birth to six children, and yet the ovaries exhibited only one cicatrix on each. On the other hand the effects of inflammation, or the bursting of small abscesses in the ovary, may produce cicatrices which cannot be distinguished from those which are caused by the escape of the impregnated ovum. There is a passage in Beck's Jurisprudence which evinces extremely little practical acquaintance with the subject, implying one error, and distinctly asserting another. His words are, "Upon examining the ovaria, if it be done a short time after the ovum has escaped from them, a corpus luteum is *generally* found, which vanishes soon after, but *leaves a scar for life*." (Medical Jurisprudence, p. 140.) Dr. Smith appears to confound the cicatrix with the corpus luteum itself, in the following passage: "In the place from which one of these bodies (ova) had been conveyed, a cicatrix was formed which received the name of corpus luteum." (Principles of Forensic Medicine, p. 489. ed. 1821.)

Having thus far described the characters of the true corpus luteum as accurately as repeated observations and dissections of a great number of women, and a much larger number of brute animals, have enabled us, we wish to declare, first, that we never in any one instance saw the corpus luteum, having the characters we have described as belonging to it, except in females who had previously been impregnated and had conceived; and our firm conviction is, that such a corpus luteum was never found in a virgin animal.

As, however, different opinions have been entertained on this subject, it becomes necessary to examine them and ascertain their value. The views entertained by those who deny the necessary connection between the formation of the corpus luteum and sexual intercourse followed by conception, are principally two. According to the one, the corpus luteum is a provision for conception, by which the ovum lodged within it is prepared and fitted for impregnation. According to the other view, the corpus luteum is properly the effect of impregnation, but may also be produced by other adventitious circumstances causing high excitement of the generative apparatus independently of sexual intercourse. The first of these opinions is generally supposed to have originated with the late Sir E. Home, but it is only justice to say that he merely revived a theory which had been exploded and lain dormant for a long series of years, as appears very clearly from a passage in Wrisberg. This writer, after stating that multiplied observations both in the human race and in quadrupeds proved that the corpus luteum was not to be found in the ovaries "ante congressum fœcundum et inde pendentem conceptionem,"

adds, "ruit itaque ingeniosum potius quam naturæ congruum, de usu et functione corporis lutei, latum judicium conceptionis matcriem ex parte sexus sequioris comprehendere et secernere." (Vide paper by Wrisberg, in Trans. Soc. Reg. Gœttingæ for 1781.) The opinion here alluded to was that of Malpighi, Santorini, Valisneri, and Bertrandi; and it is remarkable that Sir E. Home should have promulgated it anew without even noticing its former existence, and that he should have done so on the data furnished to him by a single case,* in which he examined the body of a young woman who died a few days after conception, when he found an ovum in the uterus, and a corpus luteum in one of the ovaries. From this he concludes at once that this was the commencing provision for a future conception, not the result of the former; but the reasons are not stated.

It has been already shown that a similar notion was entertained many years ago, and its accuracy disproved by observation; but it is not altogether satisfactory, nor consistent with the spirit of philosophic inquiry, to reject an opinion merely because it has been already exploded, however high may have been the authority for its rejection. We must, therefore, examine this doctrine upon its own merits, before we can refuse it our assent. In the first place, then, if such a statement were correct, corpora lutæ ought to be found in the ovaries of almost all women examined just before or during the period of life in which they are apt for conception. No one has ever asserted that this is so; and in point of fact we know it is not the case. In the second place, if such were the relation of the corpus luteum to conception, it ought to be found in a state of greater development, as the distance of time from the former conception increases: now we have demonstrative proof that exactly the contrary happens. In the third place we find that their number corresponds to the number of fœtuses which have been produced, as already explained. Such objections might easily be multiplied, but those already stated appear more than sufficient for our purpose. The other assertion, that corpora lutea may be produced independently of sexual intercourse or conception, during periods of lasciviousness, or from the stimulus of strong passions, or unnatural enjoyments, requires a very careful examination, inasmuch as, if it be really borne out by facts, the presence of the corpus luteum in the ovary would cease to be of any value whatever as a proof of impregnation; and believing, as we think we have full grounds for doing from a very long-continued examination of the subject, that the real corpus luteum is the result of conception, and of nothing but conception, we think we shall be able to show that some of the assertors of this doctrine which we impeach, have in some instances merely repeated the statements of others without examination; while others have misrepresented the opinions which they quote in their support; and others, again, have mistaken for true corpora lutea accidental formations in the ovaries, having no one character, except the colour, of the bodies which really deserve the name.

Most of the writers who advocate the production of corpora lutea without impregnation, premise as a powerful support in their favour the opinion of Blumenbach, which is thus spoken of:—"In the year 1788 Blumenbach *showed* that corpora lutea may exist in the ovaries of virgins." (See a paper by Mr. Stanley, in the Trans. Coll. Phys. Lond. vol. vi. p. 421–2.) Now, before proceeding to review any of the opinions or assertions built on the authority of this great physiologist, we must first examine what he has really said on this subject. His observations are to be found in a *Specimen Physiologiæ Comparatæ*, (Trans. Soc. Reg. Gœttingæ, vol. ix.) published in 1788, and in our opinion are very far from warranting the conclusion so generally taken for granted to result from them; first, because his own definition of the corpus luteum renders it extremely doubtful whether his observations apply to the body really deserving that name, or merely to the cicatrix on the ovary connected with it. His words are: "Notum est post fœcundum coitum in mulicre aliisque mammalibus femineis, in alterutro ovario *fissuram* reperiri cruentam, ex ruptû sub œstrum venereum unâ alterâve earum vesicularum quas Graafius pro veris ovulis venditaverat; idemquevulnusculum temporis progressu in *cicatricem abire cortice eleganter vasculoso cinctam*, atque Malpighii inde temporibus lutei corporis nomine insignitam." (Op. cit. pp. 109–10.) And, secondly, even if we are satisfied that he there speaks of the true corpus luteum, which we very much doubt, it is very remarkable that in no one part of his paper does he speak as from personal observation or examination of the subject by himself, but confines himself to physiological reasonings grounded on the facts observed by others, ("Corpora lutea in innuptis observarunt *auctores*." Op. cit. p. 113.) from the consideration of which he declares his *belief* ("Et ita corpora lutea in virgineo corpore oriri *confido*,") in one place, and his *suspicion* ("Non absimilem originem *suspicor*," Op. cit. p. 113,) in another, that the fact may be so, but he nowhere asserts that he saw an instance of it; and he adds that all the cases his reading furnished him with happened in Italian girls, whose climate he appears to suspect might have something to do with the matter. The passage in which this is expressed appears to us, even from its singularity, worth quotation here; it is as follows:—"Num climati quoque aliquod tribuendum, decidere non audio, annotans tantummodo quotquot mihi hactenus *apud auctores* occurrerunt ejusmodi haud inficiendi casus eos non nisi in Italicis virginibus observatos fuisse." (Loco citato.) Meckel, also, is by some asserted to have maintained this doctrine; but it appears to us that so far as his observations go, they afford it very little if any support at all. He commences with these words:—"The internal organs of gencration are modified not by the act of intercourse merely, but by *conception alone*. There is developed in the ovary a peculiar body called corpus luteum," (Anatomie Descriptive, &c. p. 735,) which he then describes as resulting from a change produced in one or more of the vesicles of De Graaf; and adds, "the influence of the male semen is the ordinary and regular cause of this change, which, however, it

*This he himself declares; vide Philos. Trans. 1817, p. 255.

appears, may be effected under the influence of other stimuli, *perhaps* by the imagination or unnatural enjoyments." Now it is, we think, quite plain, from the language of the above passage, that he is alluding to the opinions of others, and not stating a fact of which he had assured himself; and accordingly he immediately subjoins, "in truth, many of these rare cases, in which corpora lutea have been found in unmarried women, and in girls having the physical marks of virginity, allow the belief that the formation of these bodies *had been preceded by sexual intercourse and fecundation*." He afterwards makes an observation which, if properly understood and appreciated, would have prevented many of the absurdities which have been promulgated on this subject. "They speak," says he, "of corpora lutea which have been found in new-born or very young animals; but the obvious answer to this is, that *every yellow substance* met with in the ovary *is not a corpus luteum*." (Anatomie Descriptive, &c. p. 736.) What but the most complete mistake on this point could have induced an annotator on Beck's Medical Jurisprudence to hazard the following observation:—"A recent case has in my opinion completely overthrown the theory, that even strong passions are necessary to the formation of the corpora lutea: the subject was *not above five years old*, and the hymen of course entire; she died of tubercular disease in the lungs, yet in her ovaries were *numerous corpora lutea* as distinct as I ever saw them in the adult impregnated female." (Beck, p. 103. Note, signed *Dunlop*.) The only comment necessary to make on this statement is, simply to remark that *one* real corpus luteum, as it is found "in the adult impregnated female," is fully as large, or even larger than the ovary of a child five years old, therefore it is *impossible* that there could in such a case be several of them.

Dr. Bostock, in his very able and instructive work on physiology, (Elementary System of Physiology, vol. iii. p. 36 et seq.) gives a summary of the opinions on this subject, but avoids hazarding more than a mere hypothesis himself. It is plain, however, that he inclines to the belief "that corpora lutea are not the necessary result of impregnation." (Note, loc. cit.) But we must observe that he overstates the opinion of Blumenbach when he asserts that he "decidedly maintained" such a doctrine, which we have already shown he did not; and he is equally inaccurate in quoting Cuvier as a supporter of this physiological heresy: it is only necessary to refer to the passage quoted, (Leçons d'Anat. Comp. t. v. p. 57,) to see that Cuvier is there not speaking of the corpus luteum at all, but of the cicatrices observed on the ovaries; *and throws out a question*, whether these may not sometimes be caused by the passage of germs, under the influence of unnatural stimuli. Dr. Seymour, in his very interesting work on the ovaria, (Illustrations of some of the Diseases of the Ovaria,) has given a well-arranged summary of the conflicting opinions and theories on this subject, to which he has added some very judicious and pertinent remarks; but upon the particular question before us, he expresses himself at least vaguely. He however appears to believe in the *possibility* of the production of corpora lutea without impregnation, but nowhere asserts that he saw an instance of the kind; on the contrary, the result of his own investigations, as stated by himself, is so strongly against such a belief, that we mean to quote it in his own words as a very strong fact in our favour. "It has occurred to me," he says, "to have examined the ovaria in the human being, and in animals at the period of puberty in very many instances; many had ova ready for impregnation, large, projecting, vascular, *yet no corpora lutea were visible*." (Op. cit. p. 32.) Such, also, has been the result of our examinations of a very large number of bodies both of women and of animals, and in no one instance did we ever find a true corpus luteum except as the product of conception; and reasoning merely on the subject, we would ask, if mere imagination or highly excited desires without intercourse are capable of causing such a change in the condition of the ovary, should we not expect to find corpora lutea almost invariably in women who have been living with their husbands, or otherwise enjoying constantly the natural and perfect excitement of the generative system without conception? Of the non-occurrence of which consequence we can speak in very decided terms, from numerous opportunities of making examinations under such circumstances.

We shall now proceed to state, as briefly as possible, the opinions of those whose careful and repeated examinations of the subject fairly entitle them to the highest degree of credit. De Graaf, who is justly celebrated as an accurate anatomist and physiologist, devoted much of his attention to the generative system of the female, and in his work on this subject published in 1672, (De mulierum organis generationi inservientibus tractatus novus, Lug. Bat. 1672,) we find him thus speaking:—"Quæ vero secundum naturam, aliquando tantum, in mulierum testibus inveniuntur; sunt globuli, qui glandularum conglomeratarum adinstar ex multis particulis à centro ad circumferentiam recto quasi ductu tendentibus conflantur, et propriâ membranâ obvolvuntur. Hos globulos non omni tempore in fœmellarum testiculis existere dicimus; quia *post coitum tantum* in illis deteguntur, unus aut plures, prout animal ex illo congressu unum aut plures fœtus in lucem edet." De Graaf applied to this formation the name of corpus glandulosum, which name it retained until Malpighi changed it to that of corpus luteum on account of its colour. The great Haller paid particular attention to this point, in the investigation of which he sacrificed many sheep, goats, and cows, besides great numbers of other animals; and by opening the bodies of several at gradually prolonged intervals of time from intercourse with the male, he traced the corpus luteum from its first commencement through all its successive stages of increase and decline. (Vide Elem. Physiologiæ, vol. viii. sect. xv.) He tells us, also, that he had opened the bodies of upwards of a hundred women, and met with the corpus luteum about ten times, but never except in those who were at the time pregnant, or had brought forth children. (Vide op. min. vol. iii. p. 185, 186.) "Quotquot feminæ nullam fecundationem ante mortem passæ sunt, tot etiam incisæ nulla corpora

lutea ostendunt." Now it is to be observed that Haller continued this investigation through many years, and was perfectly well aware of the theories of Bertrandi, Valisneri, and Buffon, with the latter of whom he corresponded on the subject, and the result of his observations he embodies in two brief but most important propositions:—"Nullus unquam conceptus est absque corpore luteo." (Op. min. vol. ii. p. 458.) "Corpus luteum in virgineis animalibus nullum est, ex conceptione oritur, neque prius paratum adest." The first of these propositions has never been questioned, and the truth of the second appears to us equally incontrovertible. The observations of Blumenbach were published in 1788, and nine years afterwards, or in 1797, Dr. Haighton read before the Royal Society the details of many experiments on the subject of animal impregnation, (see Philos. Trans. for 1797, p. 159,) and thus expresses himself on this point:—"I may then say that no corpora lutea exist in virgin animals, and that, whenever they are found, they furnish incontestable proof that impregnation either does exist or has preceded." (Ibid. p. 163-4.) And again he says, "I decline trespassing on your patience, and therefore lay before you only the conclusion; which is, that in the great variety of experiments on brute animals which my physiological inquiries have led me to conduct, as well as in the extensive opportunities I have had of observing the ovaries in the human subject, I have never seen a recently formed corpus luteum unattended with some circumstance or other connecting it very evidently with impregnation." (Ibid. p. 166.) In the same year Mr. Cruikshank published his account of a series of experiments also on this subject, and we find him remarking as follows:—"These calyces, on the expulsion of the ova, enlarge and become yellow, projecting above the external surface of the ovaria, and form *corpora lutea, a certain mark of conception* in all quadrupeds, and in women themselves, whether the embryo is visible or not." (Phil. Trans. for 1797, p. 200.) William Hunter and his editor, Dr. Baillie, speak of the corpus luteum as the product of conception, but do not even mention the supposition of its possible occurrence in any other way. (Description of Gravid Uterus, 1794, pp. 14–74.)

When Mr. Angus was tried in Liverpool, in 1808, for the supposed murder of Miss Burris, great doubt arose as to whether the condition of the uterus or its appendages was such as to prove a pregnancy recently existing. "It was not until after the trial that the ovaria was examined. They were then divided in the presence of a number of physicians, and a corpus luteum distinctly perceived in one of them. Mr. Hay took the uterus and its appendages to London, and showed it to the most eminent practitioners there. He received certificates from Drs. Denman and Haighton, Messrs. Henry Cline, Charles M. Clarke, Astley Cooper, and Abernethy, all stating that it exhibited appearances that could alone be explained on the idea of an advanced state of pregnancy. *And it appears to have been universally allowed that the discovery of the corpus luteum proved the fact beyond a doubt.*" (See Report of the trial; and Edinb. Med. and Surg. Journ. vol. v. p. 220.) In addition to the authorities here cited, we may be allowed to add the result of our own observations, which have been now continued through a period of more than six years, during which time we never omitted a single opportunity within our reach for examining the bodies of women of all ages, and under all the varying circumstances of virginity, after intercourse, during gestation, and subsequent to delivery at different periods from conception; these opportunities having been afforded by more than one large hospital, as well as in private practice. We have also dissected hundreds of the inferior animals with reference to this point, and have in our museum preparations of ovaries exhibiting the corpus luteum in different conditions in the human female, and also in cows, mares, sheep, sows, goats, bitches, cats, hares, rabbits; and our firm conviction is of the truth of both Haller's propositions, viz. that "*conception never happens without the production of a corpus luteum*," and that "*the corpus luteum is never found in virgin animals, but is the effect of impregnation.*" And we think that those who have supposed or asserted that they may exist without impregnation, and of course be found in the virgin ovary, have been led into the error by confounding appearances and structures essentially different, and in fact having only one character in common, which is their colour, altogether forgetting that "every yellow substance in the ovary is not a corpus luteum." (*Meckel*, supra citat.) It is allowed by those writers that "the corpora lutea of virgins may in general be distinguished by their smaller size, and by the less extensive vascularity of the contiguous parts of the ovarium." (Mr. Stanley and Dr. Blundell.) Now we have seen several of these virgin corpora lutea, as they are unhappily called, and have preserved several specimens of them, and according to our experience they differ from those of impregnation in all the following particulars:—1. there is no prominence or enlargement of the ovary over them; 2. the external cicatrix is wanting; 3. there are often several of them in both ovaries, especially in patients who have died of tubercular diseases; 4. they are not vascular, and cannot be injected; 5. their texture is sometimes so infirm that they seem to consist merely of the remains of a coagulum, and at others appears fibrocellular and resembling that of the internal structure of the ovary, but in no instance did we ever see them presenting the soft, rich, and regularly glandular appearance which Hunter meant to express when he described them as "tender and friable like glandular flesh;" (Description of Gravid Uterus, p. 14,) 6. they have neither the central cavity, nor the radiated cicatrix which results from its closure.

[Recently, however, Dr. William Davidson (*London and Edinb. Monthly Journal of Med. Science*, Dec. 1841,) has published three dissections of females—not one of whom was pregnant, yet, in each, corpora lutea were found. They all possessed the characters assigned them by Dr. Montgomery,—a central cavity or fibrous coagulum; an oval shape, and a radiated white cicatrix in the centre, just about the central body;—the body being at the same time *immediately* under the peritoneal coat. This last point is dwelt upon

by Dr. Robert Lee, who maintains, that false corpora lutea are never observed in immediate connection with the peritoneum, a small portion of stroma intervening. One of the females had been in a weakly condition for some years, and had no children; another was unmarried, and had menstruated three days previous to her death; of the third, there was no history, but all the organs were healthy, and the Fallopian tubes and uterus were in every respect natural. Dr. Davidson expresses his confident opinion, that in none of the cases had there been impregnation prior to the appearance of these bodies; and he refers to Professors Alison, Allen Thomson, John Reid and Mr. Goodsir, in proof of the accuracy of his statement, and of their perfect resemblance to true corpora lutea. Dr. Davidson states, as the result of his investigations, that he is led to believe, that impregnation cannot take place without the appearance of a true corpus luteum, but that a true corpus luteum may appear independently of impregnation.]

Signs of Delivery.

An investigation into the proofs of delivery, whether undertaken with reference to circumstances of a social, professional, or legal nature, although not so frequently required, will be found no less important in its relations to society, nor less difficult in its details, than the examination of the proofs of pregnancy, a very clear and accurate knowledge of which latter is indispensably necessary to enable us to arrive at a satisfactory conclusion, when engaged in such an inquiry as that before us. It may, and indeed frequently does happen, that a woman with an enlarged belly arising from some purely accidental or morbid cause becomes an object of suspicion, and afterwards the sudden reduction of her size may, however unjustly, affix upon her the imputation of clandestine delivery at least; and although such charge may never be made the subject of a legal or criminal investigation, its influences would be alike unjustly prejudicial to the character of the individual, and injurious to the moral interests of society. The writer very lately saw such an instance in the case of a woman separated from her husband, who became affected with what was considered ovarian dropsy, and which enlarged the abdomen to the size of six months' pregnancy, some of the other symptoms of which state were also present. After an attack of inflammation, during which it is to be presumed the parietes of the tumour formed an adhesion with the upper part of the vagina, there took place suddenly a discharge of gelatinous fluid from that cavity, and the abdomen completely subsided in the course of a day, and the previously entertained suspicion appeared to be confirmed beyond a doubt; but on examination the woman had not about her one of the signs of delivery; yet had not the case been at once investigated, loss of reputation at the least would have inevitably, though most undeservedly, followed. In a very interesting case related by Fodcré, the life of an innocent woman was very near falling a sacrifice to the law under circumstances somewhat similar. "A young woman had her menses suddenly suppressed in consequence of a fright, and sought every aid to restore them without effect: she was at length married with a view to induce their return, which succeeded after a time, and she discharged a great quantity of fetid matters. This fact was proved by the husband and the medical attendants. It so happened just at this period that two children were found exposed and destroyed by cold; suspicion fell on this young woman, because she was known to have had an enlarged abdomen, which had very suddenly subsided. The judges of the district ordered her to be arrested and examined by a physician, a surgeon, and two midwives, who reported that they had discovered marks of delivery. In consequence of this, the unfortunate woman was condemned to death for concealing her pregnancy, and making away with her children. An appeal, however, was made to parliament against this sentence; and in consequence of two consultations, held by several physicians and surgeons of the greatest eminence, she was acquitted." (Méd. Légale, tom. i. p. 476.)

Delivery may be *concealed* with the hope of saving shame, or still more criminally with the intention of destroying the offspring; and where infanticide is charged, the law requires proof of delivery, and the finding of the child. Or again, delivery may be *feigned* for the purpose of obtaining marriage with a paramour, to gratify the wishes of a husband, or to wrest property from the lawful heir. Perhaps the most singular case of the kind on record is that related by Capuron, (Méd. Légale relat. aux accouchemens, p. 110), in which a young woman, with a view to obtaining marriage with her lover, feigned pregnancy and then delivery, and so far succeeded completely in her attempt; but after some time, being called on to produce the child, and refusing to do so, she was accused of infanticide, and brought before the criminal tribunal, where she confessed the fraud which she had practised, and the motives by which she had been actuated; but she was then called on to prove that she had never been delivered, and an investigation by medical examiners was ordered, the result of which was a report that they could find no sign of delivery of either recent or ancient date, whereupon she was acquitted and discharged. A similar instance of pretended delivery appeared not long since in a Berlin journal, as having occurred at Sirakovo in the circle of Posen, where a young woman, anxious to fulfil the ardent desire of her husband to have an heir, pretended to have been suddenly and unexpectedly delivered, and stole an infant to support the falsehood: the case was rendered more atrocious from the real mother having in consequence of the theft been subjected to the accusation of infanticide; the fact was, however, happily discovered, and the culprit consigned to the punishment due to her crime. (See Paris and Fonblanque, vol. i. p. 250.) Dr. Male tells us that a surgeon was called to a pretended labour, and a dead child presented to him, but there was no placenta; he therefore proceeded immediately to examine the woman, when he found the os tincæ in its natural state, nearly closed, and the vagina quite contracted: the fact was that the woman had never been pregnant, and the dead child was the borrowed offspring of another: it appeared that she was induced to practise the ar

tifice to appease the wrath of her husband, who frequently reproached her for her sterility.

With reference to whatever object this inquiry may be entered on, it is very important to consider, in limine, what are the limits of time within which the signs of ordinary delivery can be detected, and also whether a woman who has given birth to a child necessarily retains any mark or symptom by which her delivery can be ascertained after an interval of many months or years. With reference to the first of these questions, it must be recollected that there is a remarkable difference in the effects produced by parturition on the system of different individuals, as well as in the merely physical changes made in the condition of the parts more immediately concerned in that process, arising partly from the greater strength or tonicity in the constitution of particular persons, and the consequent rapidity with which the parts restore themselves to their original state, and partly depending on the period of pregnancy, and the size of the ovum or fœtus which has been expelled. As a general rule, however, it is agreed on by all who have directed their attention carefully to the subject, that the time within which we may expect satisfactory information has certainly expired when ten days have elapsed from the time of delivery; but we are not to assume this extension of the time suited for the inquiry as implying that we may safely postpone our examination so long, or that up to the end of that period we can obtain all the evidence we require: such is by no means the fact, and experience will soon convince us that in general within a week the condition of a healthy woman who has not sustained any accident in delivery is so restored as to render the result of any such investigation a matter of much uncertainty; many of the most marked alterations in the parts of generation disappearing, "so as to leave no trace remaining eight days after delivery." (*Baudelocque*, vol. i. p. 115. See also *Foderé*, tom. ii. p. 17. Marc, Dict. de Méd.tom. i. p. 228.) Such also was the opinion of Bohn and Albert, in conjunction with Antoine Petit and Louis, when they met in conference on the case of a woman of Nantes who was accused of infanticide, and whom they pronounced innocent on the grounds of her not having been examined as to the fact of her delivery until after the expiration of a month. We were not long since called on to examine a woman five days after delivery at the full time, and were particularly struck with the degree in which the parts had restored themselves to their natural condition, especially the os and cervix uteri, which hardly differed from their natural unimpregnated form and size. If the contents of the uterus have been prematurely expelled, the signs of delivery, at whatever time investigated, will be found indistinct in proportion to the immaturity of the ovum; so that, after abortion at an early period, so little change is made in the condition of the uterus and other parts, and the woman may exhibit otherwise so few of the signs of pregnancy even when examined within a day or two after the occurrence, that it may be found impossible to form anything approaching to a decided opinion,* excepting a very careful examination of whatever substance may have been expelled, should that be within our reach; when, if the structures of the ovum be satisfactorily detected, and we have sufficient proof that such body was expelled by the woman, there can no longer be any doubt. While writing these observations we are in attendance on a lady who miscarried a few days since, with little or no pain, but with considerable hemorrhage, at the close of the second month; and in twenty-four hours afterwards we found the os and cervix uteri almost completely restored to their natural state; the vagina and external parts hardly if at all dilated and very little relaxed; the breasts exhibited very imperfectly the appearances which accompany pregnancy, the ordinary sympathetic symptoms of which had been almost entirely absent. Now in such a case as this it would be utterly impossible to arrive at more than a very ill-established probability except by finding the ovum, which in this case was expelled entire and perfect, in which state we have preserved it.

As to the second point, or our being able to ascertain by personal examination whether a woman has ever at any former period been delivered or not: it is plain that we may be able to establish the negative of the question from the existence of some physical condition, such as a perfect hymen, which would be incompatible with the birth of a mature child; this would not, however, prove that abortion had not taken place; but such a state of imperfect development or of imperforation might be discovered, as would preclude altogether the notion of either pregnancy or delivery. But the question of most practical importance is this, — supposing a woman to have been a mother, does there remain any mark or sign by which the fact of delivery can at any future period be established? The reply to this question which experience warrants appears to be, that in a very great majority of cases we should be totally unable to discover any such certain indication of a former delivery; for although in some instances there are to be found appearances which point strongly to a probability of such an occurrence having taken place, they are very seldom indeed such as ought to be considered decisive of the question; while in other cases where parturition has occurred repeatedly, not one of the signs usually insisted on is found to have continued permanent. We very lately examined a patient who had borne five children and nursed three of them, the youngest being now five years old; the breasts were small, but neither flaccid nor pendulous; the nipples short, with not the least shade of brown colour in the areolæ, which exhibited only the delicate rose colour so often observed on that part of the virgin breast; there were neither lines nor spots of any kind on the abdomen; the os uteri was small and natural; the vagina contracted, and the fourchette perfectly entire. It should be mentioned that this lady never carried her children beyond the end of the eighth month. But the remarkable case of Aimée Perdriat, related by Foderé, (Tom. ii. 18,) shows very forcibly that the lapse of a few weeks may be sufficient to render impossible the detection of

* "Avant les deux premiers mois revolus de la grossesse surtout lorsqu'il ne s'agit pas d'une primipare, l'art ne presente aucun moyen concluant de determiner par l'examen de la femme si un avortement a eu lieu." — *Marc*, Dict. de Méd. vol. iii. p. 193.

the signs of delivery : the facts were briefly these : — On the 11th of June, early in the morning, Aimée Perdriat left her master's house and went to that of a friend named Rosina, living in the fifth story of the house, begging permission to lie down, as she was unwell with colic : in about an hour afterwards a person living in the third story heard an extraordinary noise in the water-pipe, as if a heavy body was falling forcibly through it. Aimée was not visited by any one except Rosina and another young girl, who came to ask if she wanted any thing. About five hours afterwards Rosina observed blood on the stairs and on the floor of the room, and Aimée remarked that her menses were flowing very profusely. Suspicion was excited, and on the 17th the privy was opened, when a child, placenta, and two bloody cloths were found. Two surgeons examined the body, and reported that there were no marks of violence present, except that the umbilical cord was *torn* off; that it was a full-grown child, and in their opinion had breathed after birth, and had fallen alive into the place from whence it was taken. Aimée was arrested on suspicion of being the mother of this child, and the suspicion was increased by her refusing to submit to the examination of a midwife, and having absconded from Paris : she was brought back, and on the 15th, 17th, and 27th of July, being more than a month after the supposed delivery, she was examined by Baudelocque, Dubois, Ané, Dupuytren, and Lafarge, who declared that they could not discover any sign indicative of delivery having taken place at the time in question. In consequence of this she was acquitted, the judges leaning to the side of mercy; but the circumstances of the case must impress us with a moral conviction of the woman's guilt.

The presence of shining broken streaks, like the remains of cracks, in the skin of the belly, caused by the previous distension of that part during gestation, and which when once produced are permanent, is a sign very generally acknowledged as of value; but then we have just seen that a woman may have been repeatedly delivered without the formation of any such marks; and on the other hand we know that any cause capable of stretching the abdominal integuments to the same degree may equally give rise to their production; a remarkable instance of which we lately saw in a man labouring under general dropsy, whose abdomen was literally covered with such streaks, and there were also several on the thighs, prepuce, and other parts of the body. It sometimes happens also, especially in young women of a full habit, that when the breasts have been greatly and rapidly enlarged during pregnancy or after delivery, the skin covering them is in like manner injured, and silvery lines are formed which never afterwards disappear. We have already related the particulars of a case in which we discovered, by the presence of these marks, a delivery which had taken place two years before; and this day, in consultation with Surgeon Connolly on a case of doubtful pregnancy, where previous childbearing was at first resolutely denied, the recognition of these silvery streaks induced us to press the party strongly on the subject, when she confessed that she had given birth to a child nineteen months before.

[These marks are sometimes accompanied by a brown line, extending from the pubis to the umbilicus, (Montgomery, *Signs and Symptoms of Pregnancy*, 6th edit. p. 171, Lond. 1842); and accompanying this dark abdominal line, Dr. Montgomery has, in a few instances, observed another appearance of a similar kind, which consists of a dark-coloured circle or areola, surrounding the umbilicus, extending in breadth about a quarter of an inch all round that part, and in general, but not always, varying in depth of tint according to the colour of the hair, eyes, and skin of the woman. Unlike the mammary areola, there is no turgescence or elevation of it above the surface of the surrounding skin, nor are there any prominent follicles upon its disk.

Whether it is ever produced under circumstances unconnected with pregnancy, remains to be determined by further observation. (*Dublin Journal of Medical Science*, May, 1844, p. 298; see, also, Dr. R. Turner, in *Lond. and Edinb. Monthly Journ. of Med. Sciences*, Aug. 1842, and Sept. 1844, and Dr. J. R. Cornack, *Ibid.* Feb. 1844.)]

It may be satisfactory to inquire here, whether there is any other affection of the mammæ which might give rise to such a condition of their surface. The mere accumulation of fat we certainly think would not, and the existence of diseased enlargement would not be likely to give rise to mistake; but there is one fact on this subject which deserves to be borne in recollection,—namely, that the application of leeches to the breasts as a means of restoring the menstrual discharge, lately recommended by Dr. Loudon, (Edinburgh Med. and Surg. Journ. vol. xxxviii. p. 61,) has been followed, as he tells us, by these organs becoming "swelled to an enormous degree;" and as this swelling takes place very rapidly, it seems reasonable to suppose that it might produce a similar disorganization of the integument; but we have no evidence from experience on the subject. We have, on several occasions, when examining the state of the os uteri in women who had borne children, observed that its labia felt jagged, and sometimes as if a portion had been torn and remained separated from the rest: we should attach some consideration to this state of the part, because it is not likely to be produced by the expulsion of any accidental formation from the cavity of the uterus, and we have never met with it except after childbirth. The value of the evidence to be obtained from a lacerated state of the perineum will be fully considered presently. Before proceeding to investigate in detail the present circumstances of any case submitted to us for examination, we should endeavour to possess ourselves as fully as possible of the previous history of the woman, if that be not already known to us, which may have been on the one hand such as would greatly tend to render probable the occurrence of delivery, or on the other hand to diminish, or perhaps altogether forbid, our belief in its possibility. We may, for instance, learn that she had been for several months observed to be increasing in size, and exhibiting other symptoms

of pregnancy previous to the time at which delivery was suspected to have taken place; or we may have reason to know that she had been long labouring under some form of disease, which, while it rendered the occurrence of pregnancy extremely improbable, was at the same time such as would be likely to induce many of its symptoms. The age also of the individual may be such as would tend greatly to confirm us in a negative opinion; and even supposing that we are satisfied that conception had occurred, this may in no measure facilitate our investigation, but may, on the contrary, involve us in further difficulty. It has been already shown that a woman may be pregnant, and that the fruit of her womb may be blighted at any period, but may be retained in utero until the full time is accomplished, while the size of the abdomen happening from some other accidental cause to continue increasing until the expulsion of the degenerated ovum occurs, the woman may be suspected of having brought forth a child; nay, it may even happen, however paradoxical such an assertion may at first sight appear, that pregnancy and utero-gestation, even when their full term has been nearly accomplished, and the life of the fœtus distinctly recognised, are not necessarily followed by the birth of a child, as is proved by the facts of the following very remarkable case which the writer saw about three years ago with surgeon Whitestone and Mr. Mulock. Mrs. C. of Charlemont-street became pregnant for the fourth time, and up to the seventh month matters went on favourably; but after that time she ceased to feel the motions of the child, which had been previously very active; she, however, continued to increase in size up to the end of the ninth month, when the membranes having protruded into the vagina and ruptured, a great quantity of horribly offensive fluid and gas made their escape, but no child could be discovered: in a few days afterwards the placenta and cord came away completely macerated, and all the interstitial matter so completely removed as to present a most perfect ready-made preparation of the umbilical or placental vessels, even to the most minute capillary terminations, (it is preserved in the writer's museum); but nothing remained of the child except the bones, many of which were subsequently discharged from time to time during the two years which the patient survived. The facts of this case appear to us sufficient in themselves to demonstrate the imperfection of the rule of law concerning concealment of birth, in order to prove which it is held sufficient to ascertain that there has been a pregnancy or a delivery; for in this case pregnancy was clearly ascertained, the motions of the child were strongly felt, and the full term of gestation was accomplished, yet no child was born. It may also be observed here, that should such a case as this give rise to the suspicion of infanticide, the accusation could not be sustained, because, in order to do so, the existence of the child must be proved and its body found; and in suspected cases, whether of *concealed* or *feigned* delivery, we should very carefully examine the child if possible, for the purpose of ascertaining whether its state corresponds to the supposed or pretended time of delivery, and to the other circumstances of the case, as by so doing the attempted fraud may sometimes be at once detected. If, for instance, a woman feign to have been delivered two or three days before, and produce as her own a child with the cord separated and the umbilicus quite healed; or, on the contrary, if delivery be asserted to have taken place a month before, and the cord be found still attached to the navel, such incongruities would be so far decisive against the truth of the woman's account. Other discrepancies, such as want of correspondence between the development of the child and the period of pregnancy accomplished, or the interval after delivery, will readily suggest themselves, and ought to be very carefully attended to. Having made these general observations, we have next to consider in detail the individual signs by an examination of which we may be enabled to form an opinion as to the recent occurrence of delivery, when such inquiry is instituted within a proper time after parturition is supposed to have taken place.

1. The face is generally a little paler than usual, the eyes are somewhat depressed, and not unfrequently surrounded by a slightly brownish circle, and the whole expression of the countenance resembles that of a person recovering from a slight indisposition; the pulse is more or less accelerated, the skin softer and warmer than usual, and relaxed with a moisture which has in many a peculiar and sometimes very unpleasant odour.

2. The state of the breasts ought to be a subject of particular attention, especially if examined about the third or fourth day after delivery, at which time they are generally full, tense, and hard, or even knotty under the hand, and if pressed or drawn they yield a lactiform fluid; the nipples appear turgid, and the areolæ are dark and otherwise altered, as already fully described.

3. The abdomen is found full, and its integuments greatly relaxed or even thrown into folds, especially in those who have borne several children; and we recognise those light-coloured broken streaks or cracks already mentioned, which are generally most numerous from the groins and pubes towards the umbilicus; and if the hand be pressed pretty firmly over the lower or pubic region, we feel,—4, the uterine tumour produced by the volume of the imperfectly contracted uterus, which is felt about as large as the head of a newborn child, and rising three or four inches above the brim of the pelvis, into the cavity of which it can be traced by the hand, and lying towards one or other side.

5. The state of the os uteri, vagina, and external parts, next claims our attention. By an examination per vaginam we detect the enlarged state of the uterus and its identity with the abdominal tumour, and at the same time we ascertain the condition of the os uteri, which in a recently delivered woman is found gaping open, so that two or three fingers might be introduced into it with ease; its margins are flabby and very much relaxed, and not unfrequently feel as if divided by several small fissures. If the examination happens to be made within a few hours after delivery, the patulous state of this orifice is such that its margins cannot be distinctly recognised, so that we feel at a loss to distinguish between it and the cavity of the vagina, of which it seems as if it

were a continuation. This latter part also is greatly relaxed and dilated, in consequence of which its internal surface is rendered smooth, its natural rugæ being obliterated by the recent distension of its tissues. From the same cause, also, the external parts are swollen, not unfrequently contused or even torn, especially after a first or a difficult labour, and partake of the relaxed state of the internal parts; there is also found issuing a peculiar discharge, to which we apply the name of lochia.

6. Laceration of the perineum. When a woman for the first time gives birth to a full-grown child, it frequently happens that the thin fold of integument constituting the anterior edge of the perineum, and called the fourchette, is torn, and sometimes the rent extending further backwards divides the proper substance of the perineum to a greater or less extent; this, however, is merely a contingency, which may or may not take place, and is, in fact, of rather rare occurrence, except in the simpler form first mentioned, but if recognised in the greater degree, is a very strong proof of delivery having preceded.

7. The lochia. From the time of delivery, a sanguineous discharge is eliminated from the genitals, and continues to flow for a period varying between four or five days to as many weeks, according to the peculiar habit or constitution. In general the discharge continues red for the first three or four days, and then becomes nearly colourless, or acquires a slightly brownish or dirty greenish hue, from which it is sometimes vulgarly called *green waters*, and after a week or eight days it ceases altogether. This discharge has a peculiar odour, (*Marc*, Dict. de Méd. tom. i. p. 227; *Foderé*, t. ii. p. 13,) not easily named. Loder compared it to the smell of "fish-oil;" others speak of it as a sour smell, but any one who has been much about lying-in women, especially in the wards of a lying-in hospital, must be aware of the peculiarity of this odour, which Dr. Beck informs us it has been found impossible by any artifice to destroy. (Elem. Med. Jurisp. p. 94.)

Should such an assemblage of symptoms as are here enumerated be recognised as at once existing in the case submitted for examination, no doubt could be entertained of the fact of delivery, there being, to use the words of Chaussier, "no disease or affection besides parturition which can possibly produce the whole series of signs above described;" but we may not enjoy the advantage of having before us such a satisfactory combination of proofs, and may be under the necessity of forming our opinion when only some of these signs can be detected, and others are entirely absent; and when we come to examine them separately, we shall find that they must be received in evidence with very great caution, and with various modifications of their value, by which the proofs which they afford will be found little more than merely presumptive. Thus it is obvious that the expression of the countenance, as well as the state of the pulse and skin above noticed, may be induced by any indisposition or exertion which may have depressed the bodily strength of the woman, and otherwise disordered the functions of her system. The state of the breasts has been already very fully considered in the former division of this article, so that it appears only necessary to observe here that, as on the one hand such a circumstance as the expulsion of hydatids is capable of inducing great functional activity in the mammæ and an abundant secretion of milk, so on the other hand it occasionally happens in weak, delicate women, that little or no alteration is perceived in the breasts after delivery; and it was elsewhere remarked that in such persons a similar want of sympathy is sometimes observable during pregnancy, so that the changes in the areolæ are but imperfectly established. Still we are fully warranted in considering a full breast, with abundance of milk about the third or fourth day after delivery is supposed to have taken place, as a very strong indication of such an occurrence. "It is possible," says Mr. Burns, "for this secretion to take place independently of pregnancy, but not with the appearance just described."*

The fulness of the abdomen and relaxed state of the integuments, as well as the appearance of streaks or cracks, may all arise from any cause capable of producing the same degree of distension as occurs in consequence of pregnancy, such, for instance, as dropsy or enlarged ovary, or they may be the result of a former pregnancy; while, on the other hand, they may not be found when delivery has really and recently occurred. As to the uterine tumour, we must expect to find it distinct or otherwise in proportion to the recency of the delivery and the period of pregnancy at which it took place, the fatness or tenuity of the abdominal parietes, and the degree of activity with which the contractile action of the uterine fibres may have produced, from which results in a great measure the difference in the degree of development which this tumour presents in different persons at the same interval of time after mature parturition, being smaller, and in consequence less easily felt in some at the end of four or five days than in others after double the time. Besides this, a tumour may be felt so situated, and yet may not be the uterus. To satisfy ourselves on this point, we must conjoin the examination per vaginam with that already made externally; and even when we have ascertained the exact nature of the tumour, we must recollect that it may equally arise from the organ having recently expelled a mole, a large mass of hydatids, or even a considerable accumulation of retained menstrual discharge; (see section *Suppression of the menses*,) which accidental circumstances might also produce the dilated and relaxed state of the os uteri, in which the vagina and external parts would participate. But from such causes as these there would be found neither swelling, contusion, nor laceration of the internal organs; nor could the os uteri be rendered patulous merely by increased secretion, such as long-continued leucorrhœal discharge, which sometimes induces extraordinary relaxation of the other parts. Laceration of the fourchette, although a very common occurrence in childbirth, does not always take place. We have

* Principles of Midwifery, seventh edit. p. 547. It appears proper to notice here a remarkable discrepancy between the opinion of Mr. Burns, as above stated, in his own words, and as quoted by Dr. Beck in his Elements of Medical Jurisprudence, third edit. p. 94, where he is made to assert the exact contrary, the word *impossible* being substituted for *possible*, as it stands in the text.

already spoken of a lady who bore five children without sustaining any injury to that part; and within the last few days we examined a young girl of sixteen, and of very diminutive stature, who had borne a full-grown child some months before, and the fourchette escaped uninjured. Many such instances as these have come under our observation, (see also *Marc*, loc. cit. and *Foderé*, tom. ii.); but should a laceration of the perineum be discovered, it is a proof of immense importance. We must, however, recollect that it may present itself under conditions indicating a more or less remote date as that of the delivery which caused it: thus it may be found a fresh unhealed wound, or the margins of the laceration may be perfectly healed or even callous, but quite disunited and separate from each other; or, lastly, complete union may have taken place, so that the presence of a rigid cicatrix is the only evidence remaining of the occurrence of the accident. Now should we happen, in an examination of this kind, to discover a fresh laceration of the perineum, in connection with others of the signs we have been considering, especially the relaxed and dilated state of the os uteri, vagina, and external organs, and the presence of the abdominal tumour, it ought to be considered as decisive of the fact of recent delivery; but neither of the other states of the parts would be equally conclusive as proof of a *former* delivery, because they might have been produced by causes totally unconnected with childbirth, as happened in the case of a girl who was romping with a young man, and, losing her balance, fell backwards on the point of the leg of a stool, which tore through the perineum and entered the vagina, causing a frightful laceration. Or it may have been caused by some surgical operation on the part, as in the case related by M. Berard, where it was found necessary to divide the perineum in order to accomplish the removal of a pessary which had lain several years in the vagina. (Journal Hebdomadaire, tom. i. p. 263.) About two years ago a patient applied to the writer for relief, as she was labouring under prolapse of the uterus and incontinence of urine: on examination there was also found extensive laceration of the perineum, but none of these accidents were the result of delivery. The unfortunate woman had led an abandoned life, and was the victim of a horrid outrage committed by three or four drunken ruffians, who, having first violated her, forced a broken stone into the vagina, which tore the perineum and the neck of the bladder. The stone had been removed in the hospital, but the lacerated parts never recovered the injury. As to the lochia, we cannot expect to obtain much information of a satisfactory kind from that source, especially if the examination is not made very soon after delivery. We have known the discharge cease after the second day; and even when this is not the case, we must take care that we do not confound with it some discharge of a different nature, such as the menstrual, or perhaps one of a morbid origin, from either of which, however, a careful examination of the uterus and external organs would almost certainly enable us to distinguish it.

It appears to us that we cannot more appropriately conclude this review of the ordinary signs of delivery than by quoting the words of two very distinguished writers on such subjects. "The relative value," says Dr. Paris, (Medical Jurisprudence, vol. i. p. 253,) "which each of the signs possesses will be better appreciated after we have considered the diseases whose effects may resemble them; but as a general principle we are anxious to enforce the necessity of always considering the consecutive signs of parturition collectively, and not individually; under such circumstances the practitioner can never be betrayed into an erroneous conclusion." "Other circumstances," observes Mr. Burns (Principles of Midwifery, seventh edit. p. 547), "may also concur in confirming the opinion of the practitioner; as, for instance, if the patient give an absurd account of the way in which her bulk suddenly left her, ascribing it to a perspiration, which never in a single night can carry off the great size of the abdomen in the end of a supposed pregnancy.

Delivery without consciousness.—Having in a former part of this article discussed the possibility of impregnation being effected without the woman's knowledge, as during sleep, and having alluded to the fact of delivery sometimes taking place under similar circumstances as an argument *à fortiori* in favour of the credibility of such an occurrence, it seems necessary now to consider briefly that question. That a woman may be delivered without being sensible of it, if she be at the time labouring under cerebral oppression or derangement, as in coma, in delirium, in puerperal convulsions, stupified by narcotics, (as in the celebrated case of the Countess St. Seran, *Causes Célèbres*, Cause 259), or by ardent spirits (see case by M. Deneux in the Dict. des Sciences Méd. tom. xxxi. p. 212), is a fact of repeated observation; but it is not pretended that in such instances the woman could be *afterwards* ignorant that she had been delivered. The occurrence of delivery after the life of the mother has become extinct, and consequently effected by the independent contractile power of the uterus, has been attested by so many authors of established credit, that we cannot refuse it our belief; having received the testimony of Foderé (Méd. Lég. tom. ii. p. 11), Buffon (see *Gardien*, vol. ii. p. 212), Lereux (Obs. des pertes des Sang. Obs. xiii. p. 25), Levret (Art des Accouchemens), Baudelocque (Art des Accouchemens, tom. i. p. 123, note, ed. 1822), Bichat (Anatomie Descriptive, tom. iv. p. 392, ed. 1829), and others* of equally high authority, who have recorded instances of the fact, to which for the present we shall merely refer, as below, and proceed to notice two or three facts more directly in proof of delivery during sleep or insensibility. For the first of these the writer is indebted to Dr. Douglas, one of the most experienced practitioners in this city, and whose correct and ingenious exposition of the evolution (improperly called spontaneous) of the fœtus is so well known to the profession. In a letter to the writer, Dr. Douglas states that he was called about six o'clock A. M. on the 26th September, 1828, to attend Mrs. D. of the county of W——, but then residing in

Eccles-street. On his arrival he found the house in the utmost confusion, and was told that the child had been born before the messenger was despatched for the doctor; and from the lady herself he learned that about half an hour previously she had been awakened from a natural sleep by the alarm of a daughter about five years old, who had slept with her for some nights before; and this alarm had been occasioned by the little girl feeling the movements and hearing the crying of an infant in the bed: to the mother's great surprise she found she had brought forth her child without any consciousness of the fact. Mrs. D. had had several children with favourable labours. In the London practice of Midwifery (Fifth edition, p. 87. See also Barlow's Essays on Surgery and Midwifery, p. 182), a work generally ascribed to a very distinguished practitioner, we find the following account. "A lady of great respectability, the wife of a peer of the realm, was actually delivered once in her sleep: she immediately awaked her husband, being a little alarmed at finding one more in bed than was before." To these accounts we wish to subjoin the details of a very remarkable case, from a source which leaves no doubt of the accuracy of the relation. "A fright produced by the dangerous situation of her only son, when eighteen months old, brought on in Mrs. Durant an alarming illness attended with some singular phenomena, the most singular of which respected her memory. The illness happened in July; she was then advanced six months in a state of pregnancy, and was, when perfectly insensible, delivered of a child. On awakening from the insensibility, which had continued for three days, she imagined it was the month of *January*. Her mental powers were but slightly impaired, and soon regained their former perfection; nor was her memory affected except as regarded the preceding six months: of that time she had forgotten *all* the events. Some accidental circumstance might afterwards occasionally produce a train of thought, which would bring an event of that six months to her recollection. Several of the most important, however, were never regained, *nor could she, I believe, to the hour of her death remember that she had then been pregnant.*" (Durant's Memoirs of an only Son, vol. i. p. 147.)

[A case of parturition without uneasiness, and without the least exhibition of consciousness of the child's expulsion, has been published by Mr. Rawson, (*London Lancet*, Nov. 27, 1841; and Dr. T. R. Beck, in *Amer. Journal af the Med. Sciences*, April, 1842, p. 491.) The writer was called, some years ago, to a female, who informed him, that she awoke suddenly in the night, with scarcely any uneasiness, and found both the child and placenta extruded.]

Examination after Death.—Having elsewhere described the signs of pregnancy which may be discovered after death, it will not be necessary now to say much in addition to the observations already made. In such an examination our attention should be directed to the same objects which we have been just considering as the proofs of delivery which may be recognised during life, almost all of which may be also ascertained after death, provided, as before insisted on, the investigation be undertaken within a proper time: in addition to these means, by opening the body we are enabled to satisfy ourselves more precisely of the exact condition of the uterus and its appendages. Should death take place during or immediately after the act of parturition, especially from hemorrhage, the uterus may be found lying in the abdomen, a flattened flabby bag, from eight to ten inches long, its mouth gaping wide open, so that the hand would pass through it without resistance; its parietes are soft and relaxed, its cavity often containing large coagula of blood, and its internal surface covered with the soft and pulpy remains of the decidua, which, if the part be immersed in fluid, appear as flocculent processes adhering to and springing from it in great numbers, (see preparation No. 141 in the writer's museum,) while the portion to which the placenta had been adhering is distinguished by having less of these deciduous flakes, the substance of the organ in that situation appearing as if laid bare, and exhibiting several semilunar and apparently valvular openings in its structure. But these conditions will be greatly altered should the woman have survived delivery a few days, so as to afford time for the uterus to contract; and the change produced will be in proportion to the time since delivery and the energy with which the organ may have exerted its contractile powers, so that in some instances it may be found as large at the end of a week, as in others where the examination is made within two or three days. It would therefore be very difficult, if not impossible, to assign the exact dimensions which the uterus will present at given periods after mature delivery; and should it have occurred prematurely, these dimensions will of course be thereby still further affected. When delivery has taken place at the full time, and the uterus has contracted perfectly, if an examination be made within a day or two, it will be found about seven inches long and four broad; its external surface having a vascular appearance, and not unfrequently presenting patches of a purplish colour; its substance, divided by the knife, is found from an inch to an inch and a half thick, of the consistence, and nearly of the colour, of firm muscular fibre, of which it appears to consist; and the cut surface displays the orifices of a great number of very large vessels. Its internal surface differs little from the description already given; the Fallopian tubes and ovaria, or at least one of the latter, are found turgid and vascular, and lying more confined to the sides of the uterus. At the end of a week the organ has diminished to a length of between five and six inches, and after a fortnight does not exceed five inches in length; its vascularity is diminished, and the thickness of its parietes reduced about one-third; but the density of their structure is found increased in a like proportion, so that the orifices of the vessels are much less distinct, and the colour of the muscular substance has become much paler. After this period little information is likely to be obtained from an examination of the uterus merely; for although it probably is not reduced to its original unimpregnated condition before the end of the fourth week, the alterations which can be appreciated towards the conclusion of that period are too liable to have been induced by contingent causes to allow of our attaching value to them as proof of delivery

Under such circumstances, our attention would be more profitably directed to an examination of the ovaries and the existence of the corpus luteum, the value of which has been already so fully considered that it appears now only necessary to remark, that although its existence is proof positive of previous conception, it can be received as evidence of recent delivery only when it is found in connection with other circumstances indicative of the occurrence of that event, (see report of the trial of Charles Angus for the murder of Miss Burns,) in which case it ought to be considered as a very powerfully corroborative proof.

We may sum up the substance of these observations in the following general corollaries :—

1. The signs of delivery are most distinct after the birth of a full-grown child; and least so when the uterine contents have been expelled at an early period of pregnancy.

2. The proofs are more distinct in proportion to the recency of the delivery, and any examination made after the lapse of ten days from the time of the delivery is not likely to afford satisfactory information, the most decisive signs in general disappearing within a week.

3. The third or fourth day generally presents the results of delivery very distinctly, the condition of the breasts being then most remarkable from the active secretion of milk.

4. A first delivery is more easily detected than subsequent ones.

5. We cannot safely rely on any of the signs of delivery viewed separately, but must consider them collectively, and their mutual relation and correspondence with each other, and with the other collateral circumstances of the woman's case and history.

6. The chief points of attention ought to be the state of the external parts and of the breasts.

7. There are certain physical signs which, when present, are sufficient to establish a negative decision; such are, for instance, a perfect hymen, or an imperforate state of the parts.

8. But, on the other hand, a woman may have borne children, and no one mark remain by which the fact of delivery could be proved after the lapse of even a few weeks.

9. A woman may be delivered while in a state of insensibility, or even during deep natural sleep; so that her child may perish merely from want of attention, and without any moral delinquency on her part.

W. F. Montgomery.

PROGNOSIS, *προγνώσις*, foreknowledge. The important place which in medical science is justly assigned to the faculty of foreseeing and predicting the future may be inferred from a consideration of the objects which it embraces. The principal of these are—the question whether a disease is remediable—the degree of danger which attends it — its probable duration — the circumstances which may be expected to arise during its course —its tendency to recur—and the probability of other diseases supervening.

The necessity of ministering to that instinctive anxiety with which mankind contemplate the prospect of life or death, of renovated health or protracted suffering, would of itself be sufficient to rank the faculty of prediction among the most essential qualifications of the physician. It, however, derives a stronger claim to this distinction from its important influence in the treatment of disease. Nor is there, perhaps, any one qualification more adapted to produce confidence in the patient and his attendants, and thus to insure compliance with the injunctions of the physician, than the power of predicting with accuracy what will happen in the course of a disease. Again, in a multitude of cases, how powerful an ally does he obtain if he can inspire the patient with hope by his cheering predictions! On the other hand, it often happens that, in diseases attended with little danger, there is a temporary increase of disorder and suffering. If this be foreseen and cautiously announced, disappointment and despondency, such as might retard or even prevent recovery, will be avoided. There are, besides, various circumstances incident to the progress of maladies, such as the appearance of fresh symptoms, or the supervention of some new disease, which, if foreseen, may be modified, or perhaps wholly prevented; while, in many acute affections, the anticipations of those periods and conjunctures which experience has shown to be often critical, may suggest means calculated to insure a favourable and decisive effort of nature.

It is not, however, merely in its relation to the treatment of disease that the art of prognosis is important to the physician. He will find it an influential and honourable means of promoting his own reputation; and, what he should still more value, one that may often be made subservient to the dearest and most momentous interests of his patient. That he whose days are numbered by the progress of a mortal disease, should, while his powers are adequate to the task, set his worldly concerns in order, is a position which few or none will call in question; but the necessity of preparation for another and an eternal state of being can be duly appreciated by those only who have a just perception of the awful nature of the interests at stake. Such, however, may be the physical or moral condition of the patient, or such the nature of his malady, that the announcement of danger might in many cases seem calculated to accelerate the fatal event, and to counteract the measures devised for his relief. Since, then, the issue must often be foreseen by the physician alone, the question of disclosing or concealing his anticipations will frequently place him in circumstances of the most serious responsibility. It would be foreign to the proper object of this article to attempt the delicate task of establishing general rules for the solution of such questions. It will suffice to say that the judgment of physicians would be more generally sound, and their conduct more wise, in this as well as in other parts of their professional duties, if their own minds were more deeply imbued with the importance of the truths and obligations of religion.

[Should the physician, however, have any hesitation as to the propriety of communicating his unfavourable prognosis to the patient, he ought not to hesitate to put the patient's friends in full possession of it.]

The qualifications and attainments which are essential to the art of prognosis may, in general

terms, be said to comprehend all those which give superiority in the other departments of medical science. Some, however, are more peculiarly requisite. As a foundation, the accurate discrimination of disease is obviously indispensable; and hence the necessity of those habits of close observation, and of that extensive knowledge of pathology and of the signs of disease, upon which success in diagnosis depends. But in a multitude of cases the mere recognition of a disease is a very inadequate guide to the prediction of its future course and ultimate event. Something beyond this is wanted; and here we see remarkably exemplified that practical superiority which is acquired by men of clear understanding and natural good sense, who have had the advantage of long experience and an extensive field for observation.

The difficulties which are inseparable from the subject, and the sources of error and disappointment with which it abounds, are early forced, and often painfully so, upon the attention of the physician. Before, however, experience shall have taught him the lesson, he will do well to exercise great caution in his predictions. Let him bear in mind, on the one hand, that the most formidable symptoms sometimes occur when there is no real danger; and on the other, that a moment of delusive calm is often the prelude to the sudden appearance of indications of approaching death. Let him remember, that however accurate may be his diagnosis, his estimate of what is expressively called the vis vitæ may and often must be most imperfect. If such considerations as these have their due influence on his mind, he will shrink from a rashness of prediction no less injurious to his own reputation than to the welfare of those whose life and health are intrusted to his care.

Of the grounds of Prognosis. — The first and most obvious means for predicting the event of disease is derived from an attention to the increase or diminution of its more prominent symptoms. But although common sense and experience sufficiently attest the general value of this guide, a very limited extent of observation will show that the cases in which it is an imperfect or fallacious one are numerous and important. So far, indeed, is it from uniformly indicating the ultimate event of death or recovery, that it often fails to resolve the immediate question, whether the patient is getting better or worse. Experience has taught us that the most conspicuous and distressing symptoms of many diseases are, at least in part, the result of what is termed an effort of nature to obtain relief, and that their disappearance merely announces the approaching fatal termination of the struggle. Thus the anasarca which sooner or later attends most organic diseases; the sputa, colliquative sweating, and diarrhœa of phthisis; and the saccharine urine of diabetes, often cease in the extreme stage of those maladies, but cease only to give place to death. We may perhaps refer to the same class of facts that delusive calm, sometimes accompanied by an appearance of revival, which so often precedes the fatal issue of acute diseases, as, for example, of encephalic inflammation, yellow fever, and puerperal peritonitis. Experience further shows that the disappearance of one set of symptoms is often a mere precursor of others of equal or greater severity. Thus the cold stage of ague is presently replaced by the hot; and the cessation of spasmodic asthma and of scrofulous disease of the cervical glands is frequently but the forerunner of pulmonary consumption. On the other hand, in acute diseases, a marked increase in the severity of the symptoms is a common prelude to a salutary crisis; while the crisis itself consists in the appearance or aggravation of some circumstance which, either in kind or degree, is essentially morbid.

As we thus find that the apparent increase or decrease of a malady cannot be by any means uniformly relied upon as indicating its event, we must have recourse to those materials which *experience* has collected for our guidance. In its application to the prognosis as well as to the treatment of diseases, experience presents itself in a twofold character; first, as entitling us to infer that a certain event will result from certain existing circumstances, merely because it has been ordinarily found to follow them; and, secondly, as the foundation of those generalizations and deductions which constitute the science of pathology. From the age of Hippocrates to that of Morgagni, the art of prognosis, or at least what was valuable in it, was almost exclusively founded upon the former kind of experience; for whatever was derived from pathology was always hypothetical and mostly erroneous. The writings of our own illustrious Sydenham strikingly exemplify the contrast between the value of accurate observation and the fallacy of mere speculation, however ingenious.

The cultivation of pathology in modern times has unquestionably produced an important influence upon prognosis, as well as upon every other branch of practical medicine. It would be foreign to the immediate object of this article to inquire how far that influence has been beneficial, or to what extent its benefits have been associated with mischief. It may, however, be asserted in general terms, that while, on the one hand, pathology has given an increased precision to our views of the nature, and consequently of the event of many diseases, especially of those which we call organic, yet, on the other, a propensity to generalize from inadequate data, and to attribute to the science a perfection which it has by no means attained, has unquestionably led to much error. And there can be no doubt that in the present state of medical science he who combines a simple and accurate observation of individual circumstances with an enlightened but cautious application of pathology, will be found the most sagacious in prognosis as well as the most successful in practice.

The application of experience to prognosis is greatly facilitated by the aid which nosology affords in creating abstract notions of disease apart from the peculiarities of individual cases. Hence arises a natural division of the subject into two parts. The first embraces prognosis as considered in its relation to *diagnosis*, and comprehends those general conclusions as to the future which are drawn from the known history and tendency of any given disease. The second comprehends

hose particular circumstances which belong to he individual case, not being included in the abstract notion of the disease itself.

The value of an accurate diagnosis as an index of the future is often indisputably great. In many affections it at once informs us whether we must regard the disease as curable or incurable, and whether death or recovery may be expected. Thus, when the existence of hydrophobia on the one hand, or of hysteria on the other, is clearly ascertained, we are able to predict the ultimate event with a confidence little short of certainty. If a case be identified with tuberculous phthisis or schirro-carcinoma, we at once perceive that the probability of recovery is extremely small. The great majority of diseases, including fevers generally, and indeed most acute affections, are, however, in their own nature, neither essentially curable nor incurable, fatal nor free from danger; and hence, in order to predict the result, we must take into account the circumstances of each individual case: and even when the ultimate event may be learnt from the diagnosis alone, we must still have recourse to them to determine many questions of great interest both to the patient and the physician, as the duration of the disease, the event of particular symptoms, the expectation of new ones, &c. Numerous cases also occur in practice, to which diagnosis is wholly or in a great measure inapplicable; and although in judging of the future some light may be derived from their apparent analogy to known diseases, much will necessarily depend on a consideration of individual circumstances. But not only is diagnosis in many cases unattainable, it is also often unnecessary. How much of that tact which experience gives is independent of any pretensions to accuracy in referring a case to its nosological position! This is remarkably exemplified in the anomalous affections of young females; and frequently also in those which attend the final disappearance of the menses.

It is to be observed that the limits between the two divisions under which it is proposed to arrange the several materials of prognosis are by no means always precise. It may often be doubtful whether a particular symptom is an essential character of the disease in the abstract, forming part of its diagnosis, or merely an accidental circumstance, influencing our judgment of the event. And it not unfrequently happens as a consequence of this uncertainty, that a symptom which was formerly referred to one of these two heads, is in the progress of pathology found to belong to the other.

I. Of the Prognosis of Disease as deduced from its Diagnosis.

The prognosis of particular diseases will of course be included in the articles allotted to them in the present work. It will be our more appropriate object here to generalize the subject as far as is practicable, by considering diseases as grouped together in natural families. In adopting a classification for this purpose, the point to be chiefly aimed at is its facility of application, and as no pretension is made to a perfect nosological arrangement, it is unnecessary to enter into a defence of that which will be employed in the following pages. It will be sufficient if the reader be advertised of the sense in which words employed to designate the several families of disease are used, and if the same words be always used in the same sense.

In the progress of this attempt to apply pathology to the subject of prognosis, the imperfect state of that science, or at least its limited applicability to questions of a practical nature, will often be apparent. In many diseases, and perhaps even in the majority, it may adequately account for their tendency and ultimate event; but in many others our knowledge of these points is matter of simple experience, admitting as yet neither of useful generalization nor of explication by any known laws of pathological science.

We propose to consider the different families of disease in relation to the following objects of prognosis: 1. their curability; 2. their danger; 3. the particular circumstances which may be expected to arise in their progress; 4. the supervention of new diseases; 5. their duration; 6. their liability to recur.

1. **Curability.**—The question whether a disease is remediable or not is in its nature quite distinct from that of the degree of danger which attends it. It is true that in many affections, as, for example, hydrophobia, the former appears almost solely determined by the latter, so that we have little or no reason for judging a cure to be hopeless further than our experience of the incompatibility of the disease with the preservation of life. Such cases, however, more properly belong to the next head.

Some diseases appear to be absolutely irremediable either by nature or art; in others, on the contrary, a cure may be almost certainly predicted; and between these extremes we meet with every shade of difference.

Many cases of disease which, to speak with pathological accuracy, must be called irremediable, inasmuch as the structure of the affected part cannot be perfectly restored, are yet, in a practical sense, sufficiently curable, because the alteration of structure, though permanent, is productive of no inconvenience. This is well illustrated in inflammations of serous membranes leading to adhesions of moderate extent.

Of the various forms of *idiopathic fever* (using the words in their ordinary acceptation) no one variety can be considered as in its nature incurable, since it is their general character to have a more or less determinate course and duration, and thus to cease spontaneously when they are not destructive of life. Some varieties, as the plague and yellow fever, (and perhaps the present epidemic cholera ought to be classed with them,) must, however, be deemed in a high degree incurable, because in a large proportion of cases they prove fatal, and as such they will be considered under the next head. In others, as the ordinary continued fevers of this climate and intermittents, (when they are not inveterate, and their local cause can be avoided,) general experience justifies a pretty confident expectation of recovery. The prognosis in remittent fevers is generally good in proportion as the remissions are distinct, or as the affection approaches to the character of an intermittent. As to symptomatic fevers (among which

almost all of those which are called hectic, and probably also infantile remittent fever, must be included,) their very designation implies that the question of their curability is contingent upon that of the primary disease to which they owe their origin.

It may be said of *acute inflammations* as of idiopathic fever, that none of them is, *per se*, incurable. In some, however, as for example acute hydrocephalus and laryngitis, the hope of cure is greatly diminished by the danger which attends them. In many others there is a tendency, more or less strong, to results which constitute organic disease, and which are often wholly irremediable. One of the principal of these results of inflammation is the deposition of coagulable lymph or fibrine, constituting what are called false membranes. These are most frequent in the serous membranes, where they generally cause adhesions between the opposing surfaces, and become eventually organized, and often even secreting tissues. In such an advanced state their removal is certainly beyond the reach of art or nature; and even in their earlier stages there is no evidence of absorption ever taking place, while expulsion is of course out of the question. Although adhesions of serous membranes are thus irremediable in a pathological sense, yet in a practical point of view they are ordinarily scarcely to be recognised as constituting disease. In the pleura and pericardium they are not unfrequently found to have been almost universal without having produced any appreciable inconvenience. The same may be said of the adhesions which are artificially produced by stimulant injections for the cure of hydrocele. Owing to the mechanism of the abdominal viscera, adhesions between different portions of the peritoneum appear more often to interfere with their functions, but by no means uniformly so. Inflammation of mucous surfaces exhibits much less tendency to the production of false membranes, and when they do take place, the prognosis is widely different; for by the conjoined operation of muscular contractions and mucous secretion, the membrane when formed is commonly detached and expelled, unless, as is often the case in croup, its presence has speedily caused death. Hence permanent and incurable adhesions are of rare occurrence. According to the views of Laennec, the hepatized state of the lungs consists in effusion of coagulable lymph into the air-cells, and he seems to regard it as removable by the powers of nature in every stage of its progress. It is, however, probable that the consolidation thus produced is often permanent and irremediable. In iritis there is a great tendency to the formation of organized adhesions, for which a surgical operation is the only resource. Those effusions which take place in the cellular and white fibrous tissues in inveterate gout and rheumatism, appear to be almost wholly incurable. The submucous cellular tissue is probably the seat of the thickening which constitutes permanent or organic stricture. When this is recent, mechanical pressure has some power in producing absorption; but more commonly its destruction by caustics, &c. is the only effectual remedy.

Ulceration, when it is the result of acute inflammation and does not destroy life, may be regarded as curable, though probably the integrity of the organization of the part is never perfectly restored. The deficiency is, however, very rarely discoverable, the eye being the principal exception, and that by no means a constant one. Suppuration, another result of acute inflammation, occurs in two forms. In the one it is merely an altered secretion from the surface inflamed, and unless it take place to such an extent as to be destructive of life, admits of cure. In the other it assumes the form of abscess, and, when not fatal, is remediable in various ways, as by absorption, by ulceration and the evacuation of its contents, or by the aid of surgery. Among the occasional effects of acute inflammation, softening and gangrene may be included. The former, which is principally met with in the cerebral tissue and mucous membrane of the alimentary canal, appears to consist in a disorganization wholly or in great measure irremediable. In gangrene reparation is utterly hopeless; although, when life is preserved, nature sometimes effects what may be called a cure by the separation of the diseased part. It is possible that some other alterations in the condition of parts occasionally result from acute inflammation. They will, however, be more conveniently considered under the general head of organic changes and lesions of structure.

Inflammation seems in general to be more intractable when it attacks parts of low organization, as bone, cartilage, white fibrous tissue, and consequently joints. Chronic inflammation is also commonly less under the control of remedies than acute, and more peculiarly so when, as is often the case, it is connected with a cachectic habit of body, as in scrofula, syphilis, mercurial erethism, &c. It is probably owing in part at least to the scrofulous habit with which acute hydrocephalus is so commonly connected, that every mode of treatment is found ineffectual in a considerable number of cases.

Under the term *profluvia* may be comprehended all those cases of mucous or muco-purulent discharge which cannot properly be referred to inflammation. It will thus include many forms of bronchial catarrh, diarrhœa, and perhaps dysentery, catarrhus vesicæ, and leucorrhœa. None of these is in itself incurable, but every one of them may be and often is so, from being symptomatic of some organic disease, and even when idiopathic they are often very unmanageable.

Hemorrhages, if not so profuse as to be fatal, may be considered as remediable, except when they are symptomatic of organic disease, as hæmoptysis attending tuberculous phthisis, and hæmatemesis and melæna when referable to disease of the liver or other abdominal viscera. In those forms of hemorrhage in which the effused blood finds a ready exit, the integrity of the part is left untouched; but when the effusion occurs in the substance of an organ, the case is widely different. Not only does a coagulum remain, but its presence is necessarily accompanied with a dilaceration or compression of the substance of the organ; and though the coagulum is often ultimately removed by absorption, the structure of the organ may be irreparably injured. Here, however, as in regard to the organic results of inflammation already adverted to, we must bear in mind that

what is pathologically incurable may be unattended with any appreciable morbid effects. Thus, in the cases of cerebral hemorrhage occurring in hemiplegiac attacks, every symptom of inconvenience sometimes disappears, not only before cicatrization of the breach has been effected, but even before the coagulum is absorbed. On the other hand, cases are not wanting in which the palsy has been permanent, though absorption and cicatrization had taken place. Pulmonary apoplexy, which Laennec refers to effusion into the air-cells, is considered by that pathologist to admit of perfect restoration of the healthy condition of the organ. The hematemesis of young females, and other hemorrhages which appear to be vicarious of the menstrual discharge, are striking examples of a favourable prognosis being justified under circumstances apparently the most alarming. The hemorrhagic disposition in scurvy being peculiar in its cause, is no less so in its prognosis, which wholly depends upon the power of changing the diet and other circumstances to which the disease owes its origin.

The peculiarly intractable character of most of the forms of *dropsy* is well known. Though this is chiefly, it is by no means wholly to be explained by the dropsy being merely symptomatic of some organic disease; for chronic hydrocephalus and ascites are often, and hydrocele is almost always, idiopathic, yet they are commonly but little influenced by medical treatment. Anasarca and hydrothorax are much more manageable, and even when symptomatic of organic disease, may often be removed for a time by the use of diuretic and other remedies. The powers of medicine in hydropericardium and œdema pulmonum are not much known, principally because the diagnosis of those affections is very obscure. Many forms of dropsy admit of temporary relief by surgical means; hydrocele alone (or almost so) of a permanent cure, namely, by the artificial excitement of inflammation in the serous membrane, which leads to universal adhesion of its opposing surfaces. Ovarian disease can hardly in strictness be recognised as a form of dropsy, and if it be, it is very far from affording an exception to the general intractable character of the family.

Under the designation of *cachexiæ* it will be convenient for our present purpose to include several diseases which have little in common except the impossibility of assigning them a local seat. Some of them are very little amenable to treatment. This is almost proverbially the case with scrofula in its various forms, among which may be included tuberculous disease generally. Lues and mercurial disease, when inveterate, are very difficult of cure; and diabetes, which may properly be noticed here, is well known to offer an almost hopeless prognosis. In chlorosis, on the contrary, and in scurvy, (when the circumstances which engender and maintain the disease can be reversed,) the prospect of recovery is generally good.

Under the head of *organic disease, lesions, and other changes of structure*, may be comprehended all those deviations from the natural organization of parts which are not distinctly referable to inflammation, or at least not commonly so. As a whole, they are very little remediable, though in the following enumeration many exceptions will be noticed. In hypertrophy and atrophy the prognosis varies greatly with the tissue affected; thus, by the judicious employment of remedial means, great changes may be effected in the bulk of the adipose tissue, and possibly of the muscles of locomotion; whereas in the hollow muscles, as the heart and urinary bladder, which present the two most common and well-marked instances of hypertrophy, such means seem to avail little or nothing. The contrast of the two cases perhaps countenances the opinion of some pathologists, that hypertrophy of the heart is essentially different from that increased bulk of voluntary muscles which results from their increased use.

The development of the natural tissues of the body in parts into the healthy structure of which they do not enter, is an occurrence which rarely if ever admits of remedy. Such are ossifications (with which may be conjoined exostosis and anchylosis) and cartilaginous degeneration. The fatty degeneration of the heart and liver may perhaps be included with them.

New formations are either organic or inorganic. According to most pathologists, tubercles are to be enumerated among the latter. Though the absorption of these bodies is generally admitted to be impossible, there is a mode in which nature has provided for their removal, namely, by the process of softening, or, as it is often called, ulceration; and from recent investigations it appears that the cavities which are thus produced in the lungs are occasionally obliterated by a kind of cicatrization. Of course this, in a pathological sense, is a very imperfect mode of cure, since there is no restoration of the pulmonary substance; and not only is it both rare and imperfect, but owing to the continued deposition of tuberculous matter in other parts of the lungs, it is commonly in the end unavailing.

The occasional expectoration of tubercles is far too rare and partial to modify the general prognosis of the affection. Other varieties of inorganic formations are melanosis, the contents of encysted tumours, gouty concretions, and urinary and bilious calculi. The first is in no way remediable; the others are occasionally got rid of by expulsion or ulceration, but more often not without the aid of surgery. In the opinion of Andral, medullary sarcoma is an inorganic deposition, not a degeneration: it appears to be wholly beyond the reach of remedies.

The organized new formations, as sarcomatous tumours, polypi, and hydatids, though occasionally removed by spontaneous ulceration, are in general wholly inaccessible to remedies, if we except those which surgery provides. Perhaps ovarian disease may properly be placed here. As has been already observed, it is unaffected by medicine; tapping affords but a very temporary relief; and excision is scarcely practicable except in that early stage of the disease in which it occasions far too little inconvenience to dispose the patient to submit to a formidable operation.

The organic diseases which seem to consist rather in a change or degeneration of the natural structure of the part than in any new formation, such as scirrho-carcinoma and some visceral indurations, softening of the brain and spinal cord,

mollities ossium, cataract, &c. do not admit of cure unless by surgical operations; and even then the prognosis is often bad, as in scirrho-carcinoma, and still more in medullary sarcoma, (regarded by some pathologists as a degeneration,) because the disease, though extirpated from one part, may already exist, or is liable to make its appearance in another, implying not a merely local malady, but a morbid state or tendency of the system. Indurations of the liver and spleen, occurring in inveterate ague, appear to be very little under the influence of remedies. If bronchocele and sarcocele properly belong to this division, they afford well-known exceptions to the ordinary incurability of this class of organic diseases.

Dilatations of the hollow muscles and canals, when produced by mere distension, are generally curable (supposing the cause removed) in an inverse proportion to their duration, as is seen in the urinary bladder and passages, and in the colon. Even where the dilatation is rather the effect of want of tone or contractile energy the case does not seem to be hopeless; at least Piorry alleges that he has watched the gradual diminution of dilatation of the cavities of the heart; and we know that varicose veins are sometimes reduced in size by the effects of pressure. There is reason to believe that a tympanitic state of the stomach and intestines is sometimes caused by mere want of tone, and admits of cure by proper treatment. The pathology of ileus is imperfectly known; but if, as Dr. Abercrombie inclines to infer from his researches, the only essential circumstance is a dilatation of some portion of the intestinal canal, it may properly be noticed here. The danger that attends this severe affection is well known to be great. but it cannot be regarded as incurable. Dilatation of the bronchi and enlargement of the air-cells (the pulmonary emphysema of Laennec,) are, as far as is known, incurable. Aneurism rarely consists in mere arterial dilatation: such, however, appears to be occasionally the case, especially in the aorta; and it is more particularly in this form of the disease that, in the estimation of some writers, the mode of treatment proposed by Valsalva produces a beneficial result.

Permanent strictures of canals, from effusion of lymph, have been already noticed among the effects of inflammation: those which depend on muscular contraction only are in a considerable degree remediable by mechanical means. Of permanent contractions of the hollow viscera we know little.

Breaches in the solids.—The reunion of fractured bone is generally practicable, unless in some particular states of the constitution, as pregnancy, lues, and scurvy. The only alleged ordinary exception is the neck of the thigh bone. Lacerated white fibrous tissue, as ligaments and tendons, also readily reunites. The reunion of torn muscles appears to be effected by cellular tissue, not by the reproduction of muscular fibre. It is probable that the hollow muscles and muscular canals would be generally repaired in the same manner, were not their rupture mostly attended by fatal consequences; and the same may be said of the solid viscera, as the liver, &c. In the case of blood-vessels being torn or cut through, a peculiar provision is made for the repair of the injury. The separated ends are not reunited, but the circulation is carried on through collateral branches. Divided nerves are said to be reunited by nervous tissue. Excretory ducts, the pulmonary cells, and the cutaneous and cellular tissues are all susceptible of reunion.

Ulcerations generally admit of repair by the processes of granulation and cicatrization; but least so when the system is under the influence of any of the affections already mentioned as cachectic, especially scrofula and syphilis. Of the peculiarly intractable character of ulcers in the former of these, we have instances in the articular cartilages, and in laryngeal and tracheal phthisis. With regard to excavations formed by the removal of morbid depositions, we know that healthy abscesses, when emptied, readily heal, and that even the less manageable ones are to a considerable extent curable. It has been already stated, that when life is preserved for a sufficient time, the powers of nature are occasionally adequate to the reparation of the tuberculous excavations of the lungs, and hemorrhagic cells in the brain. In some of the congenital breaches, as the hare-lip and imperfect palate, a cure may be effected by operation. In spina bifida, all attempts to cure or even palliate the affection have commonly failed; and in the case of unnatural communication between the cavities of the heart, no means can possibly be of avail.

Displacements.—The prognosis in dislocations of the joints is mostly good, provided the attempt at reduction be not too long delayed. Though the lateral curvature of the spine is often, at least in its origin, merely a displacement of certain portions of the column, it is far from being uniformly a curable affection. The angular curvature rather belongs to the head of diseased structure than to that of displacements. When invagination of the bowels is from above downwards, and no adhesions have been formed, there is good reason to believe that replacement is often spontaneously effected: when, however, adhesions have taken place, the cure must be all but hopeless. The prognosis appears to be also very bad in every circumstance of that rare form of intussusception which is from below upwards. External herniæ, when not strangulated, are mostly replaceable either spontaneously or by taxis; and when strangulated, often admit of cure by the division of the stricture. Even in cases which from adhesions or other causes cannot be relieved in this way, a sort of cure is occasionally effected, either spontaneously or designedly, by the formation of what is called an artificial anus. Diaphragmatic and other internal herniæ are wholly inaccessible to the resources of art. Prolapsus of the uterus and anus, when not invetcrate or of great extent, generally admits of cure or relief, either by means directed to increase the tone of the parts, or by mechanical support. In the latter affection, when both these means fail, excision of the protruded portion is often resorted to with success. Retroversion of the uterus is almost peculiar to the impregnated state of the organ, its immediate cause being generally distension of the urinary bladder; and when this is removed, the womb readily recovers its proper position, either spontane-

ously or by manual assistance. Inversion is perhaps never relieved except by the latter means.

When fluids escape from their natural seats by ulceration or disruption, the prognosis is very various, depending on particular circumstances. That of air into the cellular tissue, constituting external emphysema, generally ends favourably, either by spontaneous absorption or by the aid of punctures. Pneumothorax and abdominal tympanitis are much less curable, being almost always the result of organic lesions. The same may be said of effusions of urine, in which, however, remarkable instances of the curative resources of nature, when aided by the prompt and judicious interference of surgical art, are occasionally met with.

Under the general designation of *functional disorders* may be included all those which are not constantly and necessarily associated with visible changes in the condition or organization of parts. Hence, while in most of the preceding classes of disease, pathology throws more or less light upon the question of curability, in the present it almost wholly fails us. Indeed in many of the most intractable and fatal cases of these affections no morbid appearance whatever can be found after death, or at least nothing beyond slight changes in the vascularity of the part whose functions had been disturbed, and which are considered by the best pathologists rather as effects than causes of the disorder. It is true that the functional disturbance is sometimes associated with, and apparently dependent upon, inflammatory or organic disease; and where the existence of this can be known, it must of course materially influence the prognosis.

In reviewing these disorders, it will be most convenient to arrange them according to the organs or functions most prominently disturbed; and so widely do they differ in regard to their prognosis, and so insusceptible are they of any satisfactory generalization, that it will be necessary to speak of most of them individually.

Functional affections of the nervous system, including disorders of sensation and of the muscles of voluntary motion.—Two of these, viz. tetanus and hydrophobia, the pathology of which is extremely obscure, are so fatal, that in the former a cure is comparatively rare, and in the latter almost unknown. The convulsions of infants, though much less commonly fatal than the preceding, are a source of great mortality in the first years of life. In those of puerperal women there is generally a tolerably good prognosis, except where they have been produced by very profuse hemorrhage. Apoplexy is another affection often incurable by reason of its immediate fatality; and even when it does not destroy life, but disappears either spontaneously or by the use of remedies, the ultimate prognosis is greatly influenced by its known tendency to recur. Palsy and insanity, though not of themselves very frequently mortal, are often wholly incurable, and commonly but little under the influence of remedies. Palsy, at least in two of its forms, viz., hemiplegia and paraplegia, is more often connected with visible or organic changes than any other affection of this class. Yet even were the existence of such changes more certainly ascertainable than it can be, it would be necessary to use great caution in drawing inferences as to the prognosis. Thus we have the testimony of Dr. Abercrombie, that in cases of hemiplegia, the effused blood may be absorbed and even cicatrization effected, and yet the paralysis occasionally remain; while in other cases the paralysis may disappear before absorption has taken place. While so much obscurity hangs over the pathology of these affections, it need not surprise us that remarkable and unlooked-for instances of recovery, even from inveterate palsy, sometimes occur; and hence we properly draw the distinction between a bad and a hopeless prognosis. If aphonia be considered as a form of paralysis, it affords a striking instance of the uncertainty of prognosis in such affections; since, on the one hand, our anticipations of success from the use of remedies should be any thing but sanguine, while, on the other, we know that sudden and complete recovery not unfrequently takes place even when the affection has existed for years.

The prognosis in epilepsy is on the whole bad, the malady often resisting every mode of treatment, even in cases in which after death no pathological cause can be detected. On the other hand, hysteria, which sometimes very nearly resembles it, is generally curable; as in fact are most diseases which depend upon a disordered state of the menstrual function. Catalepsy is probably but a modification of hysteria, and like it generally admits of recovery; as also does chorea. Delirium tremens too often ends fatally to allow in general of a very sanguine prognosis. Hypochondriasis, which seems to be intermediate between dyspepsia and insanity, partaking in some measure of the characters of both, is probably on the whole less curable than the former, and more so than the latter.

With regard to morbid sensations, pain, though commonly but a symptom of other affections, constitutes of itself the whole character of one family of diseases, the neuralgiæ. Like the functional disorders just spoken of, they are sometimes connected with organic or other appreciable disease of some part of the nervous system, but more often not, even when they are found utterly incurable. The neuralgiæ, though often irremediable by any mode of treatment, do not on the whole justify a very unfavourable prognosis. It must, however, be much influenced by the particular seat of the pain. Thus the tic douloureux, many forms of head and back-ach, gastrodynia, and angina pectoris, are in general far less remediable affections than pleurodynia, sciatica, and lumbago. With regard to the pains of the chest, chiefly occurring in females, and referred to the intercostal nerves, the pathology is obscure, but the prognosis generally good.

With regard to functional affections of the thoracic organs, the cases ordinarily designated spasmodic croup most commonly end favourably. Some authors, however, deny the existence of the disease. Spasmodic asthma, even when apparently independent of organic disease, is confessedly a very intractable affection, the prospect of a perfect cure being on the whole but faint. The same may be said of palpitation and angina pectoris, even in the absence of organic disease; and when, as is often the case, they are associated

with it, there can be little or no hope of recovery.

Of the various modifications of functional disorder of some one or more of the digestive organs, there is none which can be regarded as in its nature incurable, though many, perhaps most of them, are often very obstinate.

The ischuria renalis, though but a functional disorder, is so often fatal that the prognosis is far from good. An exception must, however, be made as to those cases in which it is a symptom of hysteric affection. Two other morbid conditions of the renal function, namely, the secretion of albuminous urine, and the phosphatic diathesis, are perhaps mostly connected with organic disease; at any rate they are commonly very incurable maladies. Diabetes has been already noticed as being rather a constitutional disease than a mere local affection of the urinary organs.

In amenorrhœa, when it is not symptomatic of some other disease, the ultimate prognosis is generally good, though the affection is often very tedious and unmanageable. Dysmenorrhœa is perhaps even more so.

Congestions.—Although either a general or partial derangement of the balance of circulation between the arterial and venous systems may mostly form one link in the chain of circumstances which constitute diseases, it is very doubtful whether any one which is recognised in nosology can be said essentially to consist in such a state. If, however, it be otherwise, we may safely assume with respect to prognosis, that though the derangement may be sometimes destructive of life, or may eventually lead to irremediable changes of organization, it cannot constitute a disease in its nature incurable.

Parasitic animals are chiefly intestinal worms and hydatids: the former are mostly accessible to the powers of medicine; but the latter, being rarely in open canals, cannot be expelled by such means; so that the question of curability very much resolves itself into that of the practicability of a surgical operation.

2. Danger to Life.—A large number of diseases are in themselves neither so entirely destitute of danger as to cause no alarm, nor so generally fatal as to excite it in a very high degree. The estimate of danger in these affections must therefore depend on the particular circumstances of each individual case, a subject which forms the second part of the present article. There are, however, other diseases which occupy the two extremes of the scale, some being very commonly fatal, and others as commonly devoid of danger. It properly belongs to a general view of the subject of prognosis to attempt an analysis of the circumstances which determine the location of a disease in either of these two extreme classes. As we have already seen that the light which pathology throws upon the question of curability is frequently very imperfect, so will that science be often found an inadequate guide to the discovery of the extent of danger. It may be premised as a general position, that the ultimate issue of disease, whether in death or recovery, can be less certainly foreseen in acute than in chronic affections.

A Diseases, invariably or very commonly fatal, may be thus classified in relation to the circumstances which seem to determine the danger.

a. Those in which the whole system receives a sudden and overwhelming shock, most apparent in the disturbed balance of the circulation, and commonly attended with a morbid state of the circulating fluids. In this way certain forms of epidemic fever, especially the plague and yellow fever, (and the spasmodic cholera ought probably to be included,) are very often fatal in their first, or, in the language of Dr. Armstrong, their congestive stage; and sometimes even before the manifestation of any local or characteristic symptoms. It is apparently in an analogous way (though the nervous system is then often more prominently affected than the vascular) that life is sometimes suddenly extinguished by violent accidents or the agency of certain poisons.

b. Those in which organs of great importance to life, or having very extensive sympathies, are affected with inflammation or other considerable disease. Thus encephalic inflammation generally, and especially acute hydrocephalus, apoplexy, carditis, pericarditis, and organic disease of the heart, extensive phlebitis, croup, laryngitis, asphyxia, peripneumonia, peripneumonia notha, and severe or extensive disease of the gastro-intestinal mucous membrane, may all be regarded as dangerous affections. In many of them, and perhaps more particularly in those which are seated in the encephalon, even if we were always able during life to ascertain the extent and degree of the local disease or disorganization, we should have a very uncertain guide for the prognosis of danger, since the researches of pathology show that these bear no definite relation to the fatal tendency. The amount of functional disturbance probably affords a better criterion. The cases of cerebral abscess related by O'Halloran strkingly exemplify the occasional retention of life when disorganization of an important organ has proceeded to a very great extent.

c. The tendency to a fatal event seems in some diseases to be rather owing to the kind of morbid change or to its extent, than to the importance of the organ affected. Of the first kind of cause we have examples in strangulated hernia, in gangrene generally, in cynanche maligna, and perhaps in ileus; of the second, in fevers when fatal after reaction, in confluent small-pox, diffuse inflammation of the cellular tissue, and extensive peritonitis.

d. Diseases which are fatal by gradual exhaustion, including the greater part of mortal chronic diseases, as phthisis pulmonalis, laryngeal and tracheal phthisis, chronic bronchitis, empyema, tabes mesenterica, psoas abscess, some organic diseases of the liver, scirrho-carcinoma, medullary sarcoma, peritoneal accretions, ovarian disease, diabetes, &c. It is to be observed, however, that few chronic diseases terminate fatally without the supervention of disease in the bronchial or gastro-intestinal mucous membrane, especially the latter; and such a complication must undoubtedly have an important influence in determining the fatal event, and also affords a ground for predicting its approach. Profuse hemorrhages may be classed among diseases which are fatal by exhaustion

The most common examples are, the rupture of aneurisms, wounds of arteries, and puerperal hemorrhage. In some forms of apoplexy internal hemorrhage seems to be, in part at least, the immediate cause of death.

e. Intense pain, though not often of itself fatal, seems to be occasionally so. Gastrodynia perhaps affords the most frequent and decisive examples.

f. In some affections the prediction of death is rather founded upon the high probability that another and fatal disease will supervene than upon the danger which immediately arises from the existing one. The termination of ischuria renalis in apoplexy or coma is perhaps the most considerable instance.

g. The fatal tendency of puerperal peritonitis seems to be much more explicable by the peculiar condition of the system at large immediately after parturition, than by the seat or intensity of the local affection.

h. There are two diseases, namely, hydrophobia and tetanus, in a very high degree dangerous to life, yet so obscure in their pathology that it seems impracticable to unite them with any other class of mortal diseases.

B. Diseases which in themselves are rarely fatal may be thus classified:—

a. Those in which, although there be general disturbance of the nervous and circulating systems, it is moderate, and unattended by any considerable local affection, such as the ordinary intermittent and continued fevers of this country.

b. Inflammations of parts not essential to life, or not having extensive sympathies with other parts of the body; such as those of the eye, tonsils, parotids, mammæ, testicles, prostate, urethra, vagina, joints (including articular rheumatism and gout), lymphatic glands, and cellular tissue.

c. Organic affections of similar parts, as cataract and many other affections of the eye, bronchocele, hydrocele, sarcomatous and encysted tumours, and hydatids. The principal exceptions are when these affections are such as are considered specific, as scirrho-carcinoma and medullary sarcoma.

d. Certain functional disorders, as epilepsy, catalepsy, chorea, hysteria, insanity, hypochondriasis, the neuralgiæ in general, spasmodic asthma, nervous palpitation, dyspepsia, amenorrhœa, and most of those disorders which are connected with it, as chlorosis and vicarious hemorrhages. Nowhere is the imperfection of pathology, as a guide to prognosis, more apparent than in relation to this class of affections; for example, it is by experience only, and an experience which does not admit of generalization, that we judge of the wide difference in respect of danger between epilepsy, hysteria, and syncope on the one hand, and hydrophobia and tetanus on the other.

3. **Circumstances which may be expected to arise in the course of a disease.** — Although a distinction may properly be made between the appearance of new symptoms during the progress of a disease, and the supervention of new diseases, it must necessarily often be arbitrary, and sometimes obscure; since it wholly depends upon the fact of such symptoms or circumstances being or not being recognised by nosologists as separate diseases. Those which are not generally admitted as such may be arranged under three heads, *critical*, *non-critical*, and *intermediate*, that is, such as are critical in a lower degree, denoting merely a temporary alleviation of the malady.

Critical.—It is to be premised that, though a particular circumstance may in one disease be critical, it may in another, or even in a different stage of the same, be non-critical. Thus profluvia, hemorrhages, and tumours, which towards the termination of fevers are often critical, are mostly not at all so in the earlier periods of their progress. Whether critical circumstances be the cause, sign, or effect of the termination of the malady, is a question of little moment in relation to prognosis, though it may be one of much interest with regard to practice.

In treating of critical circumstances, we find a distinction of much practical importance, namely, as they indicate the permanent removal, or merely the temporary disappearance of a disease. The former are chiefly seen in continued fever and acute inflammations. Why, in such affections, one symptom or circumstance is critical rather than another, is a question involved in much obscurity. What has been called the constitution of the season appears to have considerable influence. Thus in some epidemics, fevers most commonly terminate by sweating; in others, by purging; though perhaps the most frequent mode is by copious urinary deposits. In other cases the crisis is marked by hemorrhages, abscesses, buboes, or carbuncles. There seems in fact little beyond mere experience of the prevailing tendency, to guide us in the anticipation of the particular circumstance which is likely to mark the solution. The constitutional predisposition of the individual has, however, probably some share; and also the characters of the disease, in regard to the organs or functions which are most prominently disturbed. It might indeed be conjectured that when the function of an organ has been interrupted by disease, it would, at the cessation of that disease, be renewed with augmented energy. And perhaps, as a general position, this has some foundation in truth. It seems to be in degree illustrated in the spasmodic cholera, in which affection, while the force of the disease falls very much upon the organs concerned in digestion, healthy bilious secretion often marks its favourable termination. The position must, however, be received with considerable limitation. Thus, as Laennec states, peripneumonia much more often terminates with urinary deposits than with copious sputa.

In those affections which are characterized by accessions or paroxysms returning at intervals, the termination of the paroxysm is very commonly marked by some critical circumstance. Such is the sweating of ague, the expectoration in some forms of asthma, vomiting in pyrosis, perhaps the swelling of the foot in regular gout, sleep in epilepsy, and the secretion of lithic acid in some of those painful affections of the loins which are too indiscriminately called fits of stone or gravel, there being often no evidence whatever of the passage of such concretions.

Intermediate.—In many diseases we can predict,

with more or less certainty, the occurrence of circumstances which, though they by no means denote the cessation of the malady, commonly imply a certain measure of relief. Such are dropsical effusions and hemorrhages in organic diseases and chronic inflammations of important organs, as the brain, heart, lungs, and liver. It is true that such an occurrence may itself constitute a more troublesome or immediately dangerous disease than the primary one which it tends to alleviate; and perhaps this is more particularly the case in regard to the brain, owing to the mechanism of the cranium. But even there we have strong reasons for supposing that hemorrhage occasionally, and serious effusion more often, serve to mitigate existing diseases. Effusion into the joints and neighbouring tissues, in gout and articular rheumatism, is also generally attended with some alleviation of suffering. In hectic and in remittent fevers, sweating, urinary deposits, and other secretions, make an imperfect solution; and this is observable, though in a less degree, in the daily history of even continued fevers.

Non-critical.—Under this designation may be comprehended all those circumstances, whether they be pathological changes or functional derangements, which make up the history of a disease, and which consequently may be predicted when that history is known. It is evident that prognosis of this kind is chiefly available in those affections which have a more or less determinate course and regular succession of events, the occurrence of which may be foreseen from the commencement. Such is the series of events which constitute a fit of ague, and the succession of symptoms in acute exanthemata, gout, syphilis, yellow fever, and epidemic diseases in general. The following may be instanced as some of the more considerable examples of non-critical circumstances whose occurrence may be predicted in certain kinds of disease.

a. In fevers and febrile affections generally, daily exacerbations and remissions in the symptoms may be looked for, commonly more or less nearly corresponding with the hours of sunset and sunrise. These are most conspicuous in the fevers called remittent, (as indeed their designation implies,) including infantile remittent fever, and in hectic fever, in which latter some authors distinguish two daily exacerbations, namely, about noon and sunset. Among acute inflammations, rheumatism and gout present these daily variations most conspicuously. In many cases of neuralgic affections and chronic rheumatism, the daily accessions occur at very different hours from those above named, governed by circumstances which are wholly unknown, and as to which it is impossible to generalize.

b. In inflammations, certain pathological results, varying with the tissue or organ affected, may be more or less confidently predicted. Thus inflammation of the mucous membranes, the skin, and cornea, is most liable to pass into ulceration; that of the former also often leads to softening, and occasionally, as in croup and diphtheritis, to effusion of coagulable lymph, or false membrane. Serous effusion, and the formation of false membrane resulting in adhesions, are the most common effects of inflammation of serous membranes. Erysipelatous inflammation frequently tends to gangrene; so also, in the opinion of Dr. Abercrombie, does inflammation of the muscular tissue, as in the enteritis of Cullen, and in ileus. Inflammation of the cellular tissue, kidneys, tonsils, mammæ, and, in India, that of the liver, ends chiefly in suppuration and abscess. In gout and rheumatism there is a tendency to those effusions into the white fibrous tissue which cause stiff joints, and in gonorrhœa, to the thickening which produces stricture. The pathology of phlegmasia dolens is yet involved in much obscurity; but as a point of prognosis, it deserves notice that its appearance may be often foreseen when much pain is felt in the groin soon after parturition.

c. Certain organic affections have a pathological course peculiar to themselves. Thus tubercles pass through the process of softening; scirrhus goes on to carcinoma; medullary sarcoma to hemorrhage; and ulceration of the articular cartilages to abscess and sinuses in the surrounding parts.

d. In diseases which cause long confinement to bed, and are attended with much emaciation and general loss of vital power, the occurrence of bad sores is to be apprehended. Hence they often appear in protracted fevers, phthisis pulmonalis, inveterate lues, the worst cases of insanity, &c. Somewhat analogous to this is the tendency of punctures in anasarcous limbs to cause gangrene.

e. Perhaps in most fatal chronic diseases, and certainly in phthisis pulmonalis, the appearance of slight delirium may be expected to precede death.

f. Lastly, some individual diseases are liable to circumstances peculiar to themselves, and not admitting of being generalized. Thus the disappearance of cynanche parotidœa is very commonly attended by swelling of the testes or mammæ; and inveterate ague produces indurations of the liver and spleen.

4. **Supervention of new Diseases.**—There are many varieties as to the mode in which this occurs. Thus the disappearance of the primary affection, and the development of a secondary one may be simultaneous; and if the nature of both diseases be the same, the substitution of one for the other is called metastasis or translation. Again, there may be an interval between the cessation of the first affection and the appearance of the second, as is sometimes observed when phthisis pulmonalis follows measles. Or, lastly, the two may coexist. It is to be observed, that although some diseases always supervene in the same way, this is by no means the case with all: thus disease of the heart and pericardium may either replace articular rheumatism or coexist with it. It may perhaps be assumed as a general position, subject, however, to exceptions, that when the primary disease is acute, the supervening one commonly supplants it; but when it is chronic, they go on together.

The circumstances under which new diseases supervene upon previously existing ones may be thus generalized:

a. A great degree of vascular disturbance of the system at large is very prone to end in local inflammation, its particular seat being apparently in great measure determined by the predisposition of

the part. Thus local inflammations very often occur in the course of fevers and acute exanthemata; and hysteritis or peritonitis follows profuse puerperal hemorrhage. Perhaps the frequent appearance of encephalic inflammation after violent concussion may be referred to the same head.

b. It has been already observed that chronic diseases of important organs, as the lungs, heart, brain and its membranes, liver, and mesentery, very commonly lead to disease of the gastro-intestinal and bronchial mucous membranes.

c. Diseases attended with great exhaustion, as protracted fevers, phthisis pulmonalis, diabetes, diarrhœa, and hemorrhages, generally induce anasarca. In organic diseases of important viscera, not only does dropsy take place in the cellular tissue, but also often in the cavities; and as a general though not universal rule, more especially in those with which the diseased viscera are more particularly connected. Thus hydrothorax and hydropericardium are found to supervene upon diseases of the heart and lungs; ascites upon those of the liver and abdominal viscera generally; while most organic affections of the encephalon sooner or later cause serous effusion into the ventricles, or between the membranes.

d. Many cases of supervening disease seem referable to the relation or sympathy which subsists between different tissues of the same organ, and between the external and internal parts of the same region of the body. Some of these cases are strictly metastatic; in others, the primary and secondary diseases coexist. We have examples in inflammation of the brain and its membranes ensuing upon erysipelas of the face and scalp, upon injuries of the latter, and upon otorrhœa and ophthalmia; in pleurisy occurring in peripneumony and phthisis; in the alternation of abdominal dropsy with diarrhœa or dysentery; perhaps also in anasarca following scarlatina, though in other exanthematous affections little or no tendency of this kind is observed.

e. Continuity of tissue, together with close alliance in function, is a cause of secondary diseases, most conspicuously seen in the mucous membranes. Thus, stricture of the urethra and disease of the prostate are apt to lead to disease of the bladder; and the latter, including vesical calculi, to disease of the kidneys. Common catarrh is often followed by an analogous affection of the rectum and urinary bladder, and by an herpetic affection of the upper lip; the diphtheritis of Bretonneau is very prone to pass into croup; and cynanche maligna, and occasionally pertussis, into bronchitis. An American anatomist states that he has traced the continuity of the white fibrous tissue of the limbs with that which enters into the structure of the pericardium, and thence deduces an explanation of pericarditis supervening upon rheumatism. A more simple and natural explanation appears to be that rheumatism is a disease which attacks muscles and fasciæ generally, and therefore, among the rest, occasionally affects the heart and pericardium.

f. The supervention of a new disease seems sometimes to arise from a peculiar sympathy or relation between parts which are neither contiguous, nor immediately connected in function. We have examples in the chylopoietic viscera and encephalon: thus encephalic inflammation not unfrequently ensues upon hepatitis; while the latter is sometimes produced by injuries of the head. So in fevers, meningeal inflammation is found to follow that of the gastro-intestinal mucous membrane, or the reverse. Again, infantile remittent fever is often the precursor of acute hydrocephalus.

g. When a constitutional predisposition or diathesis, such as the scrofulous or tuberculous, subsists, various diseases will either call it into activity for the first time, or, if it had previously been developed in an organ in a latent and unsuspected state, make its presence manifest. This latter is perhaps often the case in regard to the apparently exciting causes of phthisis pulmonalis. Thus all diseases which occasion great prostration of strength, as protracted fevers, exanthemata, diarrhœa, diabetes, and chlorosis, are apt, in the predisposed, to lead to tuberculous disease or external scrofula. So also inflammations or other diseases of the organs most liable to these affections will often call them forth; thus pneumonic inflammation, bronchial catarrh, and sometimes pleurisy, will pass on to phthisis pulmonalis; and inflammation of the mucous membrane of the small intestines into tabes mesenterica. Perhaps the frequent termination of spasmodic asthma in phthisis may be properly classed with the preceding facts. If the constitutional diathesis be already manifested in one organ or tissue, there will be much reason to suspect its present latent existence, and future development in others. Thus external scrofula is often the precursor of phthisis pulmonalis and tabes mesenterica; acute hydrocephalus has been observed to supersede threatened consumption; and Dr. Baron states that accretions may be expected to take place in the pleura, when they already occupy the peritoneum. So, also, the extirpation of medullary sarcoma in one organ is commonly unavailing, owing to its existence or development in others.

h. The disappearance of a morbid action or secretion of a part, or the absence of its accustomed return, is very often followed by disease in some other parts; more especially if the constitution had been long habituated to the preceding affection, or if that affection had suddenly disappeared. Cases of this kind constitute a numerous family, apparently very capricious in their individual characters, and little susceptible of useful generalization. Thus the disappearance of cutaneous diseases, profluvia, hemorrhages, purulent discharges, &c. may give rise to internal diseases of all kinds and localities, the particular nature and seat being of course very much influenced by the patient's age, habits, &c. as is illustrated by the well-known liability of aged persons, under such circumstances, to apoplexy and palsy. The following cases may be enumerated as of most frequent occurrence, and consequently of most practical importance in regard to prognosis: — the various forms of irregular gout, which (whatever be our view of the pathology of the disease) may be fairly considered to be caused by the absence or premature recession of the disorder from the extremities; hysteria and vicarious hemorrhages, resulting from amenorrhœa; the various diseases to which women are subject when they cease to menstruate, of

which scirrho-carcinoma is the most important, if not the most frequent; apoplexy and palsy, following the suppression of hemorrhoids in the aged; the alternation of gout and gravel; the occurrence of hernia humoralis, when gonorrhœa is hastily stopped by astringents; the termination of ischuria renalis in fatal coma; and the occurrence of some general and fatal disease after extirpation of a merely local one, as scirrho-carcinoma of the breast.

i. The obstruction of excretory ducts by the impaction of concrete matter frequently gives rise to disease. Thus jaundice is often caused by biliary calculi lodging in the ductus communis; and it occasionally happens that both the ureters are obstructed by calculi so as to induce ischuria renalis.

k. It is more particularly in regard to the brain and nervous system that we meet with instances of one functional disorder passing into another; though, as is often the case, both may be independent of any vascular or organic change. Thus epilepsy and chorea occasionally lead to fatuity, and mania to complete amentia.

l. There is a question of much practical interest in regard to prognosis which is entitled to some notice in this place; namely, whether there is a general tendency in functional disorders to pass into inflammation or organic disease. Notwithstanding the statements of Dr. Wilson Philip, the general experience of physicians seems to furnish a negative answer to this question, as it respects the most common of all functional disorders, — those of the digestive organs: and the same may be said of palpitations of the heart. In some of the functional disorders of the brain and nervous system, especially mania and epilepsy, pathologists have however, in a large proportion of cases, noted appearances of vascular derangement, and in many, even of disorganization; as especially Wenzels, in regard to epilepsy. Unnatural vascularity of the spinal cord is also said to be commonly found in fatal cases of tetanus and hydrophobia, and even in those of spasmodic cholera; but it is very doubtful whether it constitutes any important part of the pathology of these affections. Perhaps the same may be said of the morbid vascularity generally found in the kidneys in fatal cases of diabetes.

5. **Duration of Disease.** — The distinction between acute and chronic diseases of itself implies some sort of prognosis of their duration, yet necessarily a very imperfect one, not only because the limits of the two classes admit of no precise definition, since the same kinds of disease sometimes belong to one, sometimes to the other; but also because there is a wide range of duration among diseases referred to the same class, as for example between a twenty-one days' fever, and the worst forms of plague and spasmodic cholera. Fevers in general are considered acute affections; the only considerable exception being those which are symptomatic of organic diseases, and which mostly assume the form of hectic. Inflammations, with very few exceptions, may be either acute or chronic; and so difficult is it often found to determine to which class a given case ought to be referred, that many modern pathologists have resorted to the expedient of distinguishing a third and intermediate class, which they call subacute.

Profluvia, hemorrhages, and dropsies, diseases which have much natural affinity with inflammations, are, like them, both acute and chronic; mostly assuming the latter form when they are symptomatic of organic affections. The cachexiæ are in their nature chronic; and it is well known that when inflammation occurs in persons whose constitutions are infected with scrofulous or tuberculous disease, it commonly assumes a chronic, and at most a subacute form. Organic changes and structural lesions are necessarily chronic. Of functional disorders, some are essentially acute, as apoplexy, hydrophobia, and tetanus; others almost always chronic, as dyspepsia and hypochondriasis; many, sometimes one, sometimes the other, as paralysis and the neuralgiæ; and, lastly, some are of an intermediate or anomalous character, being chronic as a whole, but acute as to the successive paroxysms, as epilepsy and spasmodic asthma.

However uncertain the prognosis of the duration of diseases may commonly be, it is, as a general rule, much less so in acute than in chronic affections; and in some of the former it is in a considerable degree determinate. Of these we find examples in certain endemic or epidemic fevers, as well continued as intermittent and remittent; in some of the exanthemata, especially small-pox and measles, and some varieties of herpes; in acute inflammations in general, including hydrocephalus acutus; in acute profluvia, especially when epidemic, as catarrh and dysentery; in hydrophobia, tetanus, and perhaps ischuria renalis. The acute diseases, whose duration can least be calculated upon, are such as are associated with the scrofulous or tubercolous diathesis, or with secondary syphilis; those inflammations in which the inflammatory action is but slight, as pertussis; and such as are prone to shift their seat, as especially rheumatism.

Of course in proportion as the nature of the disease itself throws little light on the question of its duration, we are obliged to have recourse to the particular circumstances of each individual case, and in chronic diseases these constitute almost our sole guide.

A subsidiary means of predicting the duration of some acute diseases is derived from the knowledge of what are termed *critical days*. They have been chiefly observed in fevers, and in this work are properly treated of under that head. A general notice of the subject is all that can be attempted here.

Critical days are those on which experience has shown that fevers most commonly terminate. Authors have more particularly noted as such the third, fifth, seventh, ninth, eleventh, fourteenth, seventeenth, and twentieth, being separated in the earlier stages by periods of two days, in the later of three, and perhaps even more. Supposing the distinction to be founded in truth, we are thus able to predict with more or less confidence, at any period of a fever, that it *may* terminate on the next critical day or on any subsequent one, but that its cessation is not likely to occur at any intervening time.

The term critical days properly denotes nothing

more than the fact of termination, without any reference to its being favourable or the reverse. As to this point some authors have, however, made a distinction of days in regard to fevers generally, and with more appearance of truth as to some particular diseases. Thus Sydenham, in his admirable description of small-pox, has noted the eighth day in the distinct form, and the eleventh in the confluent, as those on which the disease is most apt to terminate fatally.

It is obvious that the mere knowledge of the existence of critical days can be of little avail for prognosis if there be no means of predicting on which of them a disease is likely to terminate. This has been supposed to be in some degree furnished by certain intervening days called *indicative*, because the occurrence of particular symptoms on them is considered to denote the termination of the affection on the next critical day.

The law which determines the series of critical days in fevers of a continued type seems to be a modification of that which regulates the periodical recurrence and termination of the paroxysms of intermittents, and the less definite course of remittents. It seems indeed as though the existence of critical days was most discernible, and consequently most available for prognosis, in proportion as fevers tend to the remittent character: and it is probably owing to the slight tendency to this character in the common continued fevers of our own country that the subject so little either occupies our attention or influences our practice.*

6. *Liability to recurrence or relapse.*—By the former of these words is properly meant the reappearance of a disease after an interval of exemption from it; by the latter, its renovation during the period of convalescence. There are very few diseases that may not, and that occasionally do not, recur when circumstances favour their production. With some, however, it very rarely happens: such are, 1. diseases which are almost uniformly fatal; 2. those epidemic fevers which appear to be partly propagated by infection or contagion, as plague, yellow fever, and typhus, and also rubeola, scarlatina, variola, pertussis, influenza, and perhaps spasmodic cholera. It is to be observed that diseases which are manifestly contagious, without being epidemic, such as syphilis, are by no means indisposed to recur. 3. Diseases which are almost peculiar to infancy and childhood, or the adult age, are of course not likely to recur in after life: such are infantile remittent fever, convulsions, porrigo, chorea, chlorosis, and perhaps epistaxis. 4. The organic results of some diseases seem to oppose an obstacle to their recurrence. Laennec asserts that this is the case with extensive adhesions from pleurisy, and it is certainly so with hydrocele when cured by exciting adhesive inflammation.

The diseases which most frequently recur may be distinguished into two classes, according as the recurrence is regular and periodical, or irregular and as it were accidental. Those which ordinarily belong to the first class are few in number, the principal being intermittent fevers. In these, the type being once known, we are able to foretel the appearance of the next fit. The prognosis must, however, be formed with some limitation, since not only may art interfere, but there appears to be very often a natural tendency in these fevers to cease spontaneously after a certain though variable number of paroxysms. Some neuralgic affections, especially headach, frequently assume a periodical character, observing the ordinary periods of intermittent fevers, and that even when they cannot be referred to malaria. The only other diseases which are often observed to return periodically are gout and spasmodic asthma, and in these the periods of recurrence form no part of the general character of the disease, but vary in each particular case. There are besides numerous other affections which occasionally observe very exact periods of return. The principal are hemorrhages, especially hemorrhoids; profluvia, as diarrhœa; and some functional disorders, as mania, epilepsy, and jaundice. But as these peculiarities belong to the individual, and not to the disease, they are of no general interest in prognosis.

The liability of diseases to return irregularly and accidentally may in general terms be ascribed to the continued influence of some circumstance which stands in the relation of a cause, either predisposing or exciting, but more commonly the former. Such causes may be thus classed:

a. Organic disease frequently gives rise to the repeated recurrence of other diseases, and these may affect either the part in which the organic disease is seated, or others more or less remote. Of the former we have examples in the liability to repeated attacks of pleurisy, peripneumony, bronchial catarrh, and hemoptysis, which attends the presence of tubercles in the lungs; in the tendency to spasmodic stricture, where permanent stricture exists; in the frequent occurrence of partial peritonitis and ascites, when the liver is organically diseased; of menorrhagia, in cases of scirrhous uterus; and of affections of the intestinal mucous membrane, in disease of the mesenteric glands. We have examples of organic disease in one part causing repeated morbid affections of other parts, in the anasarca and various hemorrhages which attend diseases of the heart, and in hæmatemesis and melæna accompanying that of the liver.

b. Nearly allied to the preceding description of cases is the well-known tendency of chronic affections to assume more or less frequently during their progress an acute character. Perhaps this is most conspicuously seen in the serous membranes, as in the pleura, peritoneum, and arachnoid membrane.

c. In many cases the liability to a particular disease on the application of slight exciting causes seems referable to some defects, not amounting to notable disease, in the vascular or nervous apparatus of a part, the result of previous attacks. It is most conspicuously seen in affections of the skin and mucous membranes, as for example in ophthalmia, cynanche tonsillaris, catarrh and bronchitis, diarrhœa and dysentery, gleet and leucorrhœa, diseases which, if they have once occurred, often leave a manifest tendency to their reproduction. In numerous other cases, however, the

* One of the most exact and satisfactory reports which has appeared of late years on the subject of critical days in the fevers of our own climate is to be found in Dr. Welsh's account of the epidemic fever of Edinburgh in 1818.

tendency in a disease to reappear seems to admit of no such pathological explanation, nor indeed of any other satisfactory one, however we may attempt to conceal our ignorance by the use of such terms as mobility, excitability, and the like. In many of these affections the vascular system is prominently disturbed. Such are erysipelas, biliary calculi and jaundice, gout, rheumatism, hemorrhoids, puerperal hemorrhage, amenorrhœa, dysmenorrhœa, phlegmasia dolens, and calculous affections of the urinary organs. In others, as palsy, epilepsy, insanity, neuralgia, palpitation, angina pectoris, spasmodic asthma, hiccup, dyspepsia, colic, and hysteria, the nervous system seems to be most affected.

d. Repeated attacks of the same disease often originate in the presence of some constitutional diathesis or depraved state of the general health. Hence the frequent recurrence of constitutional syphilis and of scrofolous affection of the glands and joints, the formation of successive crops of tubercles in the same or different organs, and the liability to scirrho-carcinoma, medullary sarcoma, carbuncles, &c.

e. Affections peculiar to certain periods of life are liable to recur during those periods, as epistaxis in childhood, and cerebral hemorrhage in old age.

f. Affections which may be traced to the interruption of some function, as hysteria and vicarious hemorrhages to suppression of the menses, may of course be expected to recur as long as the interruption continues.

The practical application of our knowledge of the liability to the recurrence of disease under the several circumstances now enumerated, consists chiefly in the avoidance of the occasional and exciting causes, since the permanent and predisposing ones are for the most part beyond our reach.

By the term *relapse* is properly signified the renewal of a disease during the period of convalescence, or before the effects of the preceding attack have entirely disappeared. Hence it is almost exclusively applied to acute diseases, especially fevers and febrile affections generally, including acute inflammations. The liability to relapse may be said in general terms to be in an inverse proportion to the completeness of the recovery. In epidemics it appears to depend in part upon their prevailing character and tendency, being much greater in some than in others; and it seems to be a general rule that when an affection, which ordinarily terminates by some marked crisis, has receded without such an occurrence, or when it has disappeared early and suddenly, without running its usual course, there is a more than common danger of relapse. It is also laid down as a maxim by Hippocrates and other writers who treat of critical days, that when fevers end on non-critical days the patients are peculiarly liable to a relapse.

II. Of the Prognosis of Disease as deduced from the particular circumstances of individual cases.

Our judgment of the future in many cases of disease is greatly influenced by the consideration of their being *primary* or *secondary*, *idiopathic* or *symptomatic*. The question of the curability and probable duration of a secondary or symptomatic affection is commonly very much involved in the prognosis of the primary one. This general rule, however, requires some limitation. Thus dropsical affections, which are symptomatic of organic disease of the heart, are not unfrequently removed, at least for a time, though the primary affection be wholly incurable. There is, however, in such cases, as has been formerly observed, great liability to a recurrence of the secondary malady.

The principal cases in which prognosis is influenced by the secondary or symptomatic character of the disease may be classed under the following heads.

a. Fever which is symptomatic of local inflammation of an acute character cannot be removed while the inflammation subsists. With regard, however, to the febrile state which attends local diseases of a more chronic and passive nature, and which often assumes the form of hectic, the same position cannot be assumed, except with considerable modification. Here we not only often meet with great spontaneous variations, the causes of which are mostly but little known, but we even find the hectic fever, to a certain extent, under the control of remedies. Thus the power of sulphuric acid to diminish the sweating is generally admitted, and the influence of bark is attested by high medical authority.

b. When local inflammation or other disease arises during the progress of continued fever, it is by no means necessary that the primary affection should cease before the secondary one can admit of removal. Indeed, when the local affection does not proceed to disorganization, it more commonly disappears before the cessation of the primary fever. It may perhaps be assumed as a general rule that the symptoms of a local affection arising in fever are more prominent and severe than those of an idiopathic affection of the same character and tendency. The treatment of fever appears to be generally influenced by this rule, and its bearing upon the question of prognosis is obvious.

c. What has been above stated in regard to hectic fever is also applicable to other affections which are symptomatic of organic diseases; that is to say, the secondary affections are not only subject to great spontaneous variations, but may often be mitigated or removed by medical art, though the primary disease be permanent and incurable. As illustrations of this we may cite those symptomatic affections which are common to organic diseases in general, namely, hemorrhages, dropsies, and affections of the bronchial and gastro-intestinal mucous membranes, and many others which are more proper to particular ones, as pleurisy and peripneumony to tuberculous phthisis; dyspepsia, pyrosis, gastrodynia, and obstipatio, to organic diseases of the stomach dysentery, to those of the liver; and dysuria, tenesmus, &c. to diseases of the urinary and genital organs.

d. Affections which are symptomatic of a deranged or interrupted function are mostly very unmanageable till the latter is restored. The most remarkable examples are furnished by the

various diseases which attend amenorrhœa, such as hysteria in all its forms, regular and irregular, hæmatemesis, obstinate vomiting, suppression of urine, &c. While the menses are absent or defective, these affections are very little under the control of remedies; but though they often assume a threatening aspect, experience teaches us that there is very little danger to life. For our knowledge of the great and extensive influence of derangements of the digestive organs in producing or maintaining various morbid affections, we are very much indebted to the sagacity of Abernethy. These affections sometimes present a formidable aspect, such as violent palpitation of the heart or interruption of its action, angina pectoris, palsy, and even a state like apoplexy; others, though less alarming, are very distressing, as neuralgia and asthma; and all of them, however generally exempt from actual danger, can only be treated with success by means which act upon the primary disorder.

e. Besides the above principal varieties of symptomatic affections, there are some more anomalous ones which deserve notice; especially worms and teething, which give rise to convulsions and various other diseases of children; and pregnancy, the origin of a long list of disorders, as vomiting, indigestion, costiveness, &c. These are all more or less subject to the general rule, that the removal of the symptomatic affection is in a great measure dependent upon that of the primary one.

f. When one disorder succeeds to or takes the place of another, the prognosis does not appear to be in general different from what it would have been if the secondary affection had occurred primarily. Dr. Cheyne, however, states that hydrocephalus supervening upon and displacing enteric disease, is more dangerous than when it occurs primarily. On the other hand, insanity is found much more often to admit of recovery when it is induced by some preceding affection, as fever or pregnancy, than when it arises spontaneously.

g. When primary and secondary diseases subsist together, the complication generally makes the prognosis additionally unfavourable; as, for example, when ulceration of the intestinal mucous membrane is superadded to phthisis pulmonalis. Sometimes, however, the fatal termination of a disease appears to be retarded by such complications, as in the well-known case of mania suspending the progress of phthisis.

In many kinds of disease the prognosis is much influenced by the nature of the *exciting causes*. The following may be noted as some of the more prominent examples of this kind:

It seems to be a general rule that epidemic disorders are more tedious, unmanageable, and dangerous, than affections of the like nature and intensity which appear sporadically, and arise from some known causes peculiar to the individual, such as exposure to cold, intemperance, &c. This is very observable in regard to affections of the bronchial and gastro-intestinal mucous membranes. There seems to be an exception to this rule in some diseases which are traceable to the influence of marsh miasmata; as, for example, neuralgic affections, which are then more curable, supposing the future action of the cause be avoided, than when they arise from cold, &c.

Local inflammations, abscesses and ulcers, when originating from an external injury or other cause which affects the part only, generally afford a much better prognosis than when they appear spontaneously; because in the latter case they have generally a constitutional origin, often of the nature of a cachectic diathesis. Tetanus, however, is more fatal when the affection is produced by a local injury than when it is referable to a cause acting on the system at large, as cold. We may here advert to the well-known fact, that in fractures or other severe local injuries, the prognosis is more unfavourable when the violence done to the part is accompanied with a general shock to the system.

In some affections of the nervous system, the prognosis appears to be partly influenced by the nature of the exciting cause, though in a way which cannot easily be explained. Thus epilepsy and insanity are said to be peculiarly intractable when they have been first brought on by fear or terror.

The mode of invasion is a point of much importance in the prognosis of many acute diseases, as fevers and febrile disorders generally, including the exanthemata. The first shock is sometimes so violent, or the progress of the disorder so rapid, that before remedial means can operate, life is extinguished, or irreparable disorganization produced. This is often seen in severe epidemic diseases, as plague, spasmodic cholera, &c.; and, among local inflammations, in meningitis and ophthalmia. If we except cases of the above description, it may be laid down as a general rule, that in proportion as the first invasion of an acute disease is well-marked and decisive, it will be found not only more controllable by remedies and shorter in duration, but also less likely to terminate fatally, or to cause permanent disorganization. On the other hand, where a disease is insidious and imperfectly developed in its commencement, remedies are generally less efficacious; and even were it otherwise, the early diagnosis is often so obscured as to prevent their being resorted to with sufficient promptitude and energy. Chronic affections are generally more or less indistinct at their commencement, and are very often so much so as to baffle all attempts at precise diagnosis. In proportion as this is the case, the prognosis is commonly unfavourable, the efficacy of remedies being mostly less decisive, and the event often revealing an extent of disease little suspected in its earlier stages.

Regularity or irregularity of progress, as a guide to prognosis, is applicable only to disorders which have a pretty marked and determinate course, as especially to the exanthemata. In these affections, any considerable deviation from the accustomed course, as a premature disappearance of the eruption, furnishes an unfavourable augury; such cases not unfrequently ending fatally, even where there has been no peculiar severity of symptoms, or other circumstances, to excite alarm. Gout is another disease in which irregularities are often the precursors of dangerous and sometimes of fatal consequences. There is one disorder which affords an apparent rather than a real ex

ception to the preceding rule. It is well known that, in intermittent fevers, changes in the accustomed hours of access of the paroxysms, whether they occur spontaneously or are caused by the use of remedies, often predict the approaching cessation of the malady.

In many diseases, especially those of a chronic character, the prospect of recovery is much influenced, and in general unfavourably so, by the length of their *past duration*. This influence seems to result from various causes, of which what may be called the force of habit is perhaps the most considerable. Its operation is conspicuously seen in many of those affections which are chiefly referrable to the nervous system, as well as in others in which the occurrence of some secretion or other form of evacuation indicates disorder of the vascular apparatus of the part affected. Of the former we have examples in epilepsy and the neuralgiæ; of the latter in hemorrhoids and leucorrhœa; while spasmodic asthma and gout are cases of a somewhat mixed character. In all these affections, and in many others of the same kind, the hope of recovery is in general small in proportion to their duration, and to the influence of habit which that duration implies. Another cause which renders the duration of a disease unfavourable to the hope of recovery, is its tendency to produce changes in the organization of parts. Perhaps all the affections commonly called nervous have more or less of this tendency, as, for example, epilepsy and asthma. It is, however, more conspicuously seen in some other diseases, as ague, gout, and rheumatism; in all of which the inveteracy of the affection is found to be increased by the production of organic changes. A third mode in which diseases become more intractable by continuance, is by diminishing the vigour of the system, and consequently its powers of resistance. This is illustrated in many kinds of chronic discharges.

The cases in which the prospect of recovery is improved by the duration of the disease are chiefly those in which it is observed to have a natural tendency to exhaust itself after long continuance. Examples are furnished by some of the chronic cutaneous diseases, as porrigo, and perhaps lepra. A tendency of the same kind is in some instances connected with age. Thus external scrofula and dyspepsia, however intractable during the earlier periods of life, are often found to diminish or disappear in mature and middle age.

With regard to the influence of the duration of disease upon its danger, it is obvious that all those affections which have a tendency to destroy life, either by inducing fatal disorganization, or by exhausting the vital powers, become increasingly dangerous in proportion as their continuance is prolonged.

Of particular Symptoms. — In the infancy of pathology a great number of symptoms which, either singly or in conjunction, are now known to indicate certain kinds of disease, merely served as guides to predict the event of individual cases. Thus, much of what Hippocrates has said on the subject of prognosis more properly belongs to that of diagnosis; and it is probably in a great measure owing to the change above noted in the relative position of these two branches of medical science, that while the latter increasingly occupies the attention of physicians, and has given birth to many valuable systematic works in our own times, the former has, for the last half century, almost ceased to be the subject of distinct treatises.* That part of prognosis which is independent of diagnosis being thus restricted in its materials, will not require a large proportional space in this article. It will be found that in local affections generally the most prominent symptoms are essentially diagnostic, and therefore foreign to our present object. In affections of a more general nature, such especially as fever, the case is different; and numerous symptoms present themselves which do not appear to be diagnostic of any particular state of disease, but which greatly influence our judgment of the event. These will necessarily occupy a prominent place in the following enumeration. It must, however, be borne in mind that in many cases our knowledge is too imperfect to enable us to determine with certainty what symptoms are properly diagnostic, and what are merely prognostic.

It is a general rule that the disappearance of the several morbid circumstances in the condition and functions of the body which constitute disease marks the approaching return of health; and, in fact, great part of the prognosis of particular diseases, as stated in systematic works, is of this kind. It seems, however, useless to extend an article like the present by an enumeration of points so self-evident. The chief exceptions to the above rule are to be found in the disappearance of one or more morbid circumstances while others remain. Indeed, in a large proportion of cases of disease, the prognosis is rather deduced from a general consideration of all the symptoms than from changes in particular ones; and hence arises an imperfection inseparable from this branch of the subject.

As the consideration of every individual morbid symptom would be at once tedious and unprofitable, it will be sufficient to particularize those which are most important and of most general application to the subject of prognosis.

Symptoms chiefly referable to the nervous system. — Delirium being one of the most common symptoms of fevers and febrile disorders generally, cannot in itself be considered unfavourable. In two of its forms, however, it indicates a threatening state of disease; namely, the delirium ferox, which perhaps mostly implies meningeal inflammation; and the muttering delirium which is one of the characters of typhus and adynamic fevers. An access or increase of delirium sometimes precedes a crisis in fevers; and, on the other hand, its cessation, though a favourable occurrence when conjoined with other marks of lessening disorder, is not unfrequently but the commencement of stupor and coma, or a part of that delusive calm which has been already adverted to as sometimes taking place before the fatal termination of many acute affections. In encephalic inflammations generally, including acute hydro-

* In a list of fifty works appended to the article *Pronostic*, in the 45th vol. of the Dict. des Sciences Médicales, which was published in 1820, thirty-five are of dates prior to 1700, (a majority of them being rather comments on Hippocrates than original treatises,) fifteen between 1700 and 1777, and none later.

cephalus, the violence and duration of the delirium is one measure of the severity and consequent danger of the disease. In acute pulmonary affections and also in jaundice, the occurrence of delirium has always been regarded as more or less alarming. That which frequently follows some local injuries does not appear to denote peculiar danger. In chronic diseases generally, particularly in phthisis pulmonalis, its occurrence is one of the most unequivocal indications of the approach of death.

Besides delirium, there are other modifications of mental disorder very common in fever and encephalic inflammations, which, when they are prominent, generally denote a severe and formidable disease. Such are, an expression of great confusion in the countenance, corresponding confusion of thought, and want of any recollection of things said or done immediately before.

The expression of great anxiety in the countenance and manner is a very unfavourable symptom in acute affections; while hope and cheerfulness, when not arising from delirium, are of good omen, being at once a cause and an indication of amendment. In many chronic affections, however, these indications are reversed. Thus in dyspepsia, jaundice, hypochondriasis, &c., anxiety and depression of spirits by no means imply any well-founded alarm; while, on the other hand, in phthisis pulmonalis there is often confidence of recovery even to the last period of existence.

A strong presentiment or anticipation of death is at all times ominous, since, apart from every consideration of its foundation, it often appears to be the cause of its own fulfilment. The same may be said of a confident anticipation of recovery, whatever be its source; for whether connected with religious impressions, or excited by the prognostics of pretenders to the healing art, it often produces the most extraordinary effects.

The opposite states of preternatural susceptibility and complete insensibility of the organs of the external senses are alike unfavourable symptoms in fevers and febrile diseases. Hence, a very contracted or dilated and immovable condition of the pupil, as well as strabismus, and that state of the eye in which it remains constantly half closed with only the white part visible, have always been considered of bad omen in such affections. It is, however, to be observed that deafness is a frequent occurrence during convalescence from fevers; and that extreme sensibility of the eyes and of the whole surface are not uncommon in hysterical affections, and of course of little moment.

In febrile disorders, sensibility to suffering, with complaint of pain, are generally favourable, while the total absence of both is always a bad symptom. Severe attacks of local pain are not unfrequently the precursors of a crisis; and a peevish sensibility to uneasiness of any kind is proverbial as an indication of approaching convalescence.

In acute inflammations severe pain in the affected part cannot in general be considered as alarming. The principal apparent exception is found in enteritis; in this case, however, the severity of the pain seems chiefly owing to a spasmodic affection of the muscular coat of the intestine. Throbbing pain is a well-known precursor of suppuration.

With regard to local pains, severe headach is an unfavourable symptom in peripneumonia notha, and perhaps in pulmonary affections generally. A sudden and violent attack of pain in the head, preceding apoplexy, denotes a very dangerous form of that disease. Very severe pain in the loins has been observed to precede the confluent form of small-pox, and at the invasion of febrile disorders in general, mostly portends an attack of considerable violence.

Pains which are prone to shift their seat, as in acute rheumatism, are generally less manageable than such as are fixed.

The sudden disappearance of pain, without any known or satisfactory cause, is always alarming, as is seen in ileus, enteritis, and hernia, although in these cases it has been too exclusively regarded as an indication of commencing gangrene.

The sensation of pricking in palsied limbs often precedes the recovery of their power.

In fever, constant lying on the back, with the legs drawn up, a continual tendency to sink down in the bed, or general rigidity of the trunk and limbs, are all unfavourable symptoms; while recumbency on the side, with occasional changes of position, and a flexible state of the muscles, are of good omen. In peritoneal inflammation great retraction of the lower extremities upon the trunk indicates a severe affection; while their occasional extension, together with the capability of sitting upright, are sure signs of the subsidence of the inflammation.

Convulsions and spasmodic affections are much worse symptoms in the advanced than in the early stages of fevers, and are generally less alarming in women and children than in adult males. Indeed, in young children (as Sydenham remarked in small-pox) their occurrence at the invasion of febrile disorders is often rather favourable than otherwise. In general it is not so much their severity as their continuance and frequent recurrence which imply danger. Among the different forms of convulsive movements, subsultus tendinum, picking at the bed-clothes, &c.; tremours of the hands and lips, and grinding of the teeth, are more peculiarly alarming, as being common indications of approaching dissolution.

A propensity to keep the hands and feet out of bed, and the trunk uncovered, commonly denotes a state of severe disease. Any form of paralysis occurring in fevers and acute inflammations is generally more or less alarming. Severe rigors are not ordinarily unfavourable in acute affections, as they tend to produce speedy reaction. In chronic diseases they are much more often so, mostly implying internal suppuration.

Extreme debility, or loss of muscular power, almost always justifies alarm.

Somnolence, occurring at an advanced stage of febrile affections, if it be associated with other indications of their decline, and especially if it follow some form of crisis, is highly favourable. In other circumstances, however, it is often but the beginning of a state of torpor, eventually passing into fatal coma. Sleep which is hurried or disturbed by convulsive startings, or in which

the eyes are half open, showing the white part only, or in which the lower jaw drops, is of bad omen. Constant wakefulness is always an unfavourable symptom.

Of all the indications of approaching death, and of all the forms in which it takes place, perhaps none is more general than coma. Yet coma does not invariably portend death. In fevers attended with much cerebral disorder, and in idiopathic affections of the encephalon, more particularly in children, it is not unfrequently recovered from. In pulmonary affections it is almost always a fatal symptom.

Circulating system.—The prognosis deduced from the action of the heart and arteries varies greatly in different diseases and under different circumstances. Extreme weakness, with great frequency, and perhaps irregularity of the pulse, is one of the most constant precursors of death. The principal exception is found in cases of profuse hemorrhage, when the pulse often remains full and vibrating, almost to the last moments of life. A very great degree of frequency, such as any excess above 150, is of itself almost invariably indicative of danger; and under some circumstances, especially after parturition, a pulse even above 100 justifies the apprehension of impending mischief. In cerebral affections more particularly, the pulse is liable to great variations of character, and these are sometimes valuable for the purposes of prognosis. Thus in apoplexy, the transition from a small, weak, and rapid pulse, to a full, strong, and labouring one, is always alarming. Mere irregularity or intermissions, especially when met with in advanced life, are by no means so alarming as is popularly supposed; and the most vehement palpitations of the heart, alternating with protracted intermissions, are met with in those sympathetic affections of the organ which experience shows to be attended with little real danger.

Syncope is chiefly an alarming symptom when it is connected with disease of the heart and larger arteries, or is the result of extreme exhaustion, as from profuse hemorrhage.

With regard to morbid conditions of the blood, the separation of a thick and tenacious coat of fibrine, with great contraction of the coagulum and concavity of its surface, though mostly indicative of active local inflammation, or of a general inflammatory diathesis, cannot in itself be regarded as an indication of danger. The dark, grumous, or pitch-like blood, which is commonly met with in the first or congestive stage of severe febrile disorders, and in some other affections, though a much more formidable appearance, does not by any means necessarily imply great danger, since it often disappears after one or more bleedings, as in diabetes and fevers. That dissolved and watery state of the blood in which it resembles claret, and is scarcely or not at all coagulable, such as is often seen in purpura, is much more alarming than either of the two preceding.

The prognosis of hemorrhage, when considered as a separate disease, has already been adverted to. As a symptom of other diseases, it is often an important guide to their prognosis. In febrile disorders it is presented under two very different aspects; in the one appearing as a critical symptom, and denoting the favourable termination of the malady, in the other constituting an occurrence of much danger. The distinction between the two must of course be drawn from the circumstances under which the hemorrhage takes place. The modifications of hemorrhage in which the characters of the effused fluid are widely different from those of natural blood, such as the black vomit of yellow fever, and the alvine discharges in melæna, are always alarming. Hemorrhages, when occurring in chronic affections, as in tuberculous disease of the lungs, scirrho-cancer, organic disease of the heart, &c. though often producing some temporary relief, must always be considered as very unfavourable in relation to the ultimate event.

Respiratory system.—There is scarcely any more certain indication of severe and dangerous disease than great disturbance of the respiratory function, if we except those cases in which it is referable to some spasmodic affection of the organs, of which asthma is the most considerable example. Slow, labouring, and irregular, or hurried and feeble respiration, is one of the most common precursors of death; and where an audible rattle in the throat is also heard, that event may almost invariably be pronounced near at hand. Spasmodic asthma is almost the only case in which orthopnœa does not imply a formidable state of disease. Stertorous breathing, which is in a great measure peculiar to severe cerebral disorders, is always more or less alarming. Extremely fetid breath in fever is unfavourable.

Deep sighing is sometimes one of the most prominent indications of such a degree of exhaustion after hemorrhage as leaves little hope of rallying. Moaning is chiefly observed in children, especially in acute hydrocephalus, and is an unfavourable symptom.

In chronic diseases which are attended with cough and expectoration, these symptoms are commonly observed to cease before death. In aged persons, the disappearance of an habitual bronchial affection is always an alarming circumstance, being generally a prelude to some fatal attack, as of apoplexy. The prognosis to be drawn from the character of the sputa varies with the nature of the existing disease. Thus purulent expectoration, when associated with tuberculous disease, is always alarming; in chronic bronchitis it is less decidedly so, and in acute bronchial affections supervening upon fevers, &c. the prognosis is often good, even though the excretion be of an alarming extent and duration. This is perhaps still more strikingly observed in abscess of the liver communicating with the bronchial tubes.

Notwithstanding many occasional exceptions, it cannot be doubted that the frequent appearance of blood mingled with the sputa must be ordinarily regarded as a very unfavourable circumstance. Fetid and black sputa are always alarming.

Hiccup occasionally precedes a favourable reaction in some cases of acute disease, as for example in the epidemic cholera; but much more commonly it appears in the advanced stages of both acute and chronic diseases as one of the indications of approaching death. In fevers, hurried or inarticulate and scarcely intelligible speech is generally an unfavourable symptom.

Organs of digestion.—Perhaps there is no one single circumstance indicative of approaching convalescence of such general value as the return of the tongue to its natural state; and, on the other hand, its various deviations from that state are among our best guides for judging of the severity and probable danger of disease. A perfectly dry tongue, whether its surface be polished, of a livid red or mahogany colour, or covered with a rough coating of brown or blackish fur, is at all times indicative of severe and commonly of more or less dangerous disease; while a natural degree of moisture almost always justifies a favourable augury, except in affections which are attended by hectic fever. Redness of the tip and edges, with unnaturally prominent papillæ, is too commonly met with in acute diseases of most kinds, especially those in which there is much irritation of the gastro-intestinal mucous membrane, to be regarded as unfavourable, unless when it is peculiarly vivid; but in chronic affections, continued redness of the tongue commonly justifies apprehensions. Paleness is not a threatening symptom, except when it is one of the results of alarming hemorrhage. The temperature of the tongue may be said in general terms to furnish the same indications as that of the surface of the body. An extreme degree of coldness has lately excited much attention, as being one of the characteristic symptoms of the present epidemic cholera in its worst form. The opposite states of tremour and of rigidity with retraction of the tongue, have been noted as unfavourable symptoms in fevers and other acute diseases.

Brown or black sordes on the lips, gums, and teeth, always denote more or less of danger. Bleeding of the gums, when it occurs late in fever, as part of a general hemorrhagic disposition, is an unfavourable symptom. The lips, more than any other part of the body, indicate, by their livid or purple colour in severe affections of the organs of respiration and circulation, that want of arterialization of the blood which is almost always an alarming symptom. Coldness of the lips and dropping of the under lip and jaw are among the features of the well-known facies Hippocratica. Salivation has been occasionally noted as critical in fevers, but its value in prognosis is chiefly seen in those cases in which mercury is given with a view to produce its specific effect. In these its appearance often warrants the anticipation of a favourable change. An aphthous state of the mouth and fauces is generally alarming, but more decidedly so in chronic than in acute affections, and in adults than in children.

An unnatural degree of appetite is sometimes observed to precede the development of severe inflammation of the gastro-intestinal mucous membrane; but it is chiefly in relation to convalescence that the appetite is a guide to prognosis, for its return, after a period of more or less complete anorexia, is one of the surest marks of returning health. Its sudden manifestation by a craving for some particular kind of food, after severe and protracted cases of fever, has been often noted as the first indication of a recovery which had previously been despaired of.

In febrile disorders, intense thirst always implies a severe affection; but its apparent absence, under circumstances in which it is ordinarily present, is a far more dangerous symptom, as being one of the indications of a general loss of physical sensibility.

Difficulty of swallowing, when it results from loss of muscular power in the œsophagus, as in the advanced stages of fever, hydrocephalus, apoplexy, and palsy, is always an alarming symptom. When it arises from some mechanical obstruction, the prognosis of course varies with the nature of the particular cause.

Vomiting at the commencement of febrile disorders cannot be considered as unfavourable, unless it be very severe and protracted. In acute affections of the gastric mucous membrane, as well as in chronic diseases of the stomach, it may furnish some kind of index, though certainly no constant or sure one, of their severity and danger. Though vomiting is popularly associated with the very notion of cholera, it is of itself no guide to our prognosis in that affection, being sometimes very inconsiderable in its most severe form. In cerebral affections, unless it recur very frequently, it is often rather a favourable symptom, indicating the continuance of physical sensibility. Thus, after concussion, it is one of the marks which distinguish a temporary suspension of the cerebral functions from a state of perfect coma. Vomiting of black matter, as in yellow fever, and sometimes in melæna,—of putrid, as in some very bad forms of fever,—and of fæces, as in ileus, are all alarming symptoms. There is one case in which the most protracted and uncontrollable vomiting can hardly be considered dangerous,—namely, when it is merely a symptom of hysteria. In pregnant women, especially in the earlier months of gestation, it is often peculiarly obstinate, without giving just occasion for alarm.

Diarrhœa, like other evacuations in febrile affections, occurs under two circumstances widely differing in their relation to prognosis; being in the one case critical, in the other a cause of exhaustion, often connected with severe disease, or even disorganization of the intestinal mucous membrane. Diarrhœa is also critical in some other affections, especially those in which there is much congestion in the abdominal viscera; it also often marks the solution of colic and ileus. Black and pitchy stools are sometimes met with in critical diarrhœa; but when evacuations of this kind, instead of marking the solution of an acute disease, assume a more chronic character, as in melæna, the prognosis is mostly unfavourable. Hemorrhage from the bowels is sometimes critical in fevers, but is more often one of the results of a general hemorrhagic tendency which rapidly exhausts the patient's remaining strength. Involuntary passage of the fæces is under all circumstances alarming. Diarrhœa, when it occurs in the course of chronic affections, commonly renders the prognosis increasingly unfavourable, because it mostly implies the extension of disease to the intestinal mucous membrane. In such cases it very often ceases for some hours before death, being one indication of the approach of that event. Great insensibility to the action of emetics and purgatives is an alarming symptom in many cerebral diseases, especially the acute hydrocephalus.

A tympanitic state of the intestines generally

denotes danger, though, as Dr. Abercrombie has shown, it is sometimes recovered from, even after enteric inflammation. A hard and tumefied state of the hypochondria and neighbouring parts has been long noted as an unfavourable symptom, except when, as is sometimes the case, it precedes a critical diarrhœa. Great depression of the abdomen, so as to make the hips and false ribs prominent, is indicative of a threatening state of things.

If we except some severe affections of the biliary system, met with in tropical climates, a copious secretion of healthy bile is generally a favourable occurrence. It was found very commonly to indicate recovery in the epidemic cholera of India. Jaundice supervening upon cerebral affections is a dangerous symptom, and in all circumstances that form of it in which the skin is of a green hue justifies a much worse prognosis than the yellow variety.

Urinary organs.—A complete, or nearly complete cessation of the renal function is always dangerous (unless when it is part of an hysteric affection), being very commonly followed by fatal coma, both in children and adults. Retention of urine from insensibility of the bladder is an unfavourable symptom in fever; its involuntary discharge is still more so. Bloody urine is occasionally critical; but more often, like other hemorrhages in the advanced stages of fever, it implies danger. Of all the occurrences which mark a crisis or favourable turns in fevers and inflammations generally, none is more common in our own climate than a copious deposition in the urine, sometimes of bilious matter, but more often of sediments chiefly composed of lithic acid and its compounds. In fact, when these are found in the urine, the prognosis is almost always good, except in cases attended with hectic fever; whereas the presence of the earthy phosphates as commonly denotes a dangerous state of disease. Albuminous urine is decidedly unfavourable, unless perhaps in cases of acute dropsy.

Sexual organs.—Amenorrhœa is a common attendant of many chronic diseases, generally occurring when they have made some progress, and, consequently, giving a more unfavourable aspect to their prognosis.

[Diseases which occur during *menstruation*, and especially during *pregnancy*, are esteemed to be more severe, and, as a general rule, such is the case. Moreover, in the latter condition, they may induce abortion or premature delivery, and thus add to the danger. Yet certain affections seem to be masked, if not arrested, in their development by pregnancy,—tuberculosis of the lungs, for example, which appears, however, to run its course with more fearful rapidity after *delivery*. The *puerperal state* adds likewise to the danger of serious maladies.]

The skin and subcutaneous tissue.—As to colour; a livid, purple, or leaden hue of the lips, cheeks, and surface generally, is a symptom indicative of danger. Sudden and frequent variations of colour, a circumscribed flush of the cheeks, extreme pallor, or its opposite, a very high degree of redness (when not from an exanthematous affection), are all unfavourable symptoms. In eruptive disorders, the imperfect development of the eruption, an unnatural colour of it, or its premature recession, are circumstances generally more or less alarming.

As to temperature: the opposite extremes of intense heat and death-like coldness are both alarming. Partial and unequal distribution of heat, especially that sense of burning which is often felt in the palms and soles in chronic diseases attended with hectic fever, and also frequent variations of temperature, are unfavourable. Coldness of the extremities is one of the most familiarly known precursors of death.

Moderate perspiration, if diffused over the body, attended with warmth, and not of long duration, is almost never unfavourable, and often critical. The extremes of dryness and moisture, like those of heat and cold, are dangerous; but especially moisture when combined with cold, as in the cold clammy sweats which often denote approaching death. Partial sweating, as of the head, chest, or extremities (as in phthisis pulmonalis), is always unfavourable. Perspiration of a fetid, cadaverous, or urinous odour, is an alarming symptom, unless it belong to hysteria. Sydenham observes that sweating in the eruptive fever of small-pox denotes that the disease will assume the distinct form.

Petechiæ, vibices, ecchymosis, and oozing of blood from the skin, are always unfavourable symptoms, though in various degrees, depending on the particular circumstances in which they occur.

When œdema or anasarca appears towards the termination or after the cessation of acute diseases, it is rarely alarming, and sometimes even critical. On the contrary, in chronic and organic diseases it always confirms a prognosis already unfavourable; and in these cases its disappearance, especially when sudden, is often among the indications of approaching death.

Abscesses and buboes are analogous to excretions, inasmuch as they are sometimes critical, and at others complications, which increase the patient's sufferings and accelerate his death.

Emaciation, even to a great degree, is rarely alarming when it is the result of acute disease. In chronic diseases it almost invariably renders a prognosis otherwise doubtful decidedly bad. To this head may be referred most of those well-known features which together make up the facies Hippocratica; namely, the pointed nose, sunk eyes, shrivelled ears, hollow temples, and pale, black, livid, or lead-coloured complexion.

Besides those circumstances which form part of the disease itself, there are others pertaining to the individual affected, the climate which he inhabits, the season of the year, &c., which often materially influence our prognosis of the future. An attempt to estimate the value of all these with any degree of exactness would involve an extension of this article much beyond the limits assigned to it; a brief review of some of the leading facts is, therefore, all that can be attempted.

Sex.—The influence which sex has on prognosis is chiefly referable to affections of the sexual organs, especially of the female. It has been already observed that the various morbid affections which are apt to occur about puberty, or for a few years after, when the menses are absent, such as hemorrhages, disorders of the digestive organs, different modifications of hysteria, &c., though often and apparently threatening, scarcely ever

justify alarm, unless they are complicated with fixed local disease, as tubercles, &c. The sudden suppression of the menses, as from cold or terror, is very apt to be followed by severe and often tedious disorders of various kinds. Morbid affections occurring about the time of the natural cessation of the menses often assume a very formidable character, resulting in scirrhus of the womb or breast, or organic disease of other kinds. The various local affections which immediately depend on pregnancy, as vomiting, hemorrhoids, œdema, &c., may of course be expected to cease with their cause. Affections which partially or wholly disappear when conception takes place, such as phthisis and mania, may be expected to return with equal or increased energy after parturition. The prognosis is considered more unfavourable in pregnant females than in others, after severe injuries and surgical operations. It may perhaps be assumed as a general rule, that in the pregnant state local affections are attended with symptoms more severe than those which would accompany them under other circumstances. If this be the case, a better prognosis will commonly be justified than would otherwise be admissible.

Age.—The difficulties and sources of error which are inseparable from the art of prognosis under all circumstances, are found to be peculiarly great in relation to the diseases of infants and young children. In them the powers of life are easily overwhelmed or soon exhausted, so that affections comparatively slight are often rapidly and unexpectedly fatal. On the other hand, if those powers are adequate to sustain the shock of disease till its violence is past, recovery commonly takes place with peculiar rapidity, and often under circumstances apparently the most desperate. [*Nil desperandum* should be the maxim of the physician in such cases; for, to use the language of Chomel, (art. *Prognostic*, in *Dict. de Méd.* xxvi. 120, Paris, 1842,) childhood is the age of resurrections.] If there be one class of affections more peculiarly dangerous than others in the earliest periods of life, it is severe injuries of the skin. Hence burns, even of very inconsiderable extent, and small blisters, are often speedily fatal. As children are much more constitutionally disposed to convulsive affections than adults, their appearance is in general proportionately less alarming; yet violent, or rather protracted convulsions, are very frequently the cause of death in infants. In childhood, the prognosis of surgical operations is commonly better than at other periods of life, not only from the activity with which nature carries on the work of reparation, but from the absence of those depressing moral causes which at a more mature age so often paralyse the physical powers of the system.

[Yet under two years of age, owing to the great impressibility of the nervous system of the infant, there is greater danger of convulsions from operations.]

In many affections the prognosis is greatly modified by the advance from childhood to puberty, and from puberty to manhood and old age. Of the former we have illustrations in rickets, external scrofula, epilepsy, chorea, and urinary calculus, disorders which, when most intractable in childhood, often spontaneously improve and disappear about puberty, or in the approach to manhood. On the other hand, some of these very affections, especially epilepsy and chorea, not unfrequently make their first appearance about puberty. Indigestion arising from irritability of the gastric mucous membrane, a very common and troublesome affection in youth and early manhood, often gradually diminishes with the approach of middle age. The influence which age has upon prognosis in regard to many disorders of females has been already considered in connection with the subject of sex.

The circumstances of very advanced age are in some respects analogous to those of infancy, in others conspicuously different. The vital powers being feeble, as in infants, are easily overwhelmed; and thus comparatively slight attacks of bronchial inflammation, vomiting, purging, hemorrhage, &c., often rapidly carry off old people. But unlike the early stages of life, the power of reparation being no less feeble than that of resistance, many diseases, not in their nature directly fatal, admit of very imperfect recovery, and often lead to gradual exhaustion. Fractures and ulcers of the surface are examples familiar to every one.

[On these points, much light has been thrown by statistical observers, to which a brief allusion only can be made here. It is well known, that more males are born than females; yet there are manifestly, during the early stages of life, agencies operating to reduce the proportion of the male sex. (Quetelet, *Sur l'Homme*, i. 43, Paris, 1835, and Burdach's *Physiologie*, u. s. w., i. 587, Leipz. 1835, cited in the writer's *Human Physiology*, 5th edit. ii. 406, Philad. 1844.) The investigations of Dr. Emerson (*Amer. Journ. of the Med. Sciences*, for Nov. 1835, p. 56) exhibit clearly that the greater liability of males to accidents does not furnish a sufficient reason for their greater mortality;—the deaths reported in the Philadelphia bills, under the head of casualties, constituting but a small proportion of the whole mortality; and this, when burns and scalds are included—being more considerable in the case of the female. The gross male mortality under the twentieth year, for the ten years from 1821 to 1830 inclusive, exceeded the female in the ratio of 7.94 per cent. The diseases which seemed to be particularly obnoxious to the male sex, were, according to the Philadelphia bills, the following, arranged in the order of their decreasing mortality.—Inflammation of the brain; inflammation of the bowels; bronchitis; croup; inflammation of the lungs; fevers of all kinds, except scarlet fever; convulsions; general dropsy; dropsy of the head, and small-pox. To these sources of mortality may be added those under the head of casualties, and others vaguely designated debility, decay, &c. The few cases in which the deaths of females predominated were—consumption, dropsy of the chest, scarlet fever, burns and scalds, and hooping-cough. The excellent reports of the Registrar General of Births, Deaths, and Marriages in England, contain much valuable information on these heads.]

Constitution, &c.—In persons of vigorous constitution, whether of the sanguine or melancholic temperament, acute disease, though often vehement and proportionately dangerous, is commonly more under the control of active remedial measures than in those of an opposite habit. Weak

ness and exhaustion not only predispose to inflammatory affections, but also render their occurrence more dangerous, even though they may not assume a very intense or vehement aspect. Persons of delicate form, lax fibre, and great physical and moral susceptibility, whether their temperament be sanguine or melancholic, are so liable, under various and even opposite circumstances, to become the subjects of tuberculous or other incurable chronic affections, that in them the prognosis of the ultimate event of even slight disease is generally more or less doubtful.

In almost all circumstances of disease, a calm, equable, and cheerful constitution of the mind tends to render the prognosis more favourable. In cases of severe local injury, and after surgical operations, it is found to be of the greatest importance.

With regard to habits of life, the peculiar danger of almost every severe malady, and often of trivial ones, to gluttons, drunkards, debauchees, and those whose constitutions are broken down by alternations of excess and privation, is familiarly known. This partly explains the frequent extreme fatality of epidemic diseases in armies, especially when moral causes of a distressing nature are superadded.

[Yet when fatal epidemics threaten, the abandonment of long-cherished habits — even if intrinsically objectionable — may render the individual more liable to their attacks, and the supervening disease more dangerous.]

In connection with facts of this kind may be mentioned the far greater mortality of infants in foundling than in lying-in hospitals; no advantages of cleanliness, ventilation, and care, compensating for the deprivation of that mode of sustenance which nature has provided for the first months of existence.

A marked constitutional tendency to any form of disease, whether it be hereditary, or common to the members of a family of the same generation without the suspicion of inheritance, or peculiar to the individual himself, generally makes the prognosis decidedly more unfavourable.

Climate often influences the prognosis of disease. In tropical countries acute diseases are commonly more vehement in their attack, more rapid in their progress, and more apt speedily to cause irremediable disorganization, than in temperate regions. Hence the prognosis is generally more unfavourable. On the other hand, temperate climates, being most commonly variable, are more apt, by the repeated irritation which frequent and sudden changes in the atmosphere produce, to render chronic affections, and especially those of the respiratory organs, incurable and ultimately fatal. It is perhaps from a similar cause that syphilis is generally found to be a more tractable and less dangerous disease in warm than in cold and variable climates. Convulsive affections, particularly tetanus, are observed to be not only more common, but also more fatal in hot countries. It is hardly necessary to state, that in all diseases which arise from local causes, such as marsh miasmata, the prognosis must be proportionately bad while exposure to the influence of those causes continues.

Season.—The season of the year is a circumstance of some importance in the prognosis of many diseases. This is in general better in spring and summer than in autumn and winter; and more particularly so with regard to scrofulous and tuberculous affections, and diseases of the pulmonary organs, among which measles may be enumerated. It has been noted from the time of Hippocrates downwards, that autumnal intermittents are both more severe and more intractable than vernal ones; and perhaps the observation is generally applicable to continued fevers, though subject to much exception.

The varieties of form and character assumed by diseases in different years, or at different periods of the same year, and which mark what Sydenham calls the constitution of the season, of course involve corresponding varieties in the prognosis. The experienced tendency of particular epidemics is indeed often found to be a more certain guide to our judgment of the future than could be derived from a mere consideration of the symptoms; a point which has been justly insisted on by Dr. Gooch in relation to puerperal or peritoneal fever.

[The *special* prognosis, in case of epidemics, will be regulated, to a certain extent, by the *general* prognosis. At the incursion of certain epidemics, as of cholera and scarlatina, the prognosis is, at times, exceedingly unfavourable; but after awhile the disease becomes milder, and often—it must be borne in mind—not owing to improved treatment. Such was the fact with the cholera especially, which not unfrequently on its first appearance destroyed almost all that were attacked by it; and afterwards became much mitigated; yet, under all treatment, the mortality from it was, on the whole, much the same every where. (See Cholera.)]

The effect of remedies previously tried, whether in the same person under a preceding similar attack, or (as in the case of epidemics) in other persons similarly affected, is often an important aid to our prognosis of their operation, and consequently of the event of the malady.

Edward Ash.

PROLAPSUS UTERI. See Uterus, Diseases of the.

PRURIGO, (from *prurigo*, itching,) is arranged by Willan, Alibert, Rayer, Biett, and others, as a papular affection of the skin; but the eruption is generally very obscure. There are several varieties of prurigo. The chief characteristic of all of them is severe itching, augmented by sudden exposure to heat. Where any eruption appears, and this seldom occurs except when the spot which itches is rubbed or scratched, the papulæ are of the same colour as the adjoining cuticle. The disease is either *general* or *local*, and as such only shall we regard it, as we are decidedly of opinion that the three *general* species designated by Willan, under the terms *mitis*, *formicans*, and *senilis*, are merely modifications of the same affection, depending on the state of the individual, and the changes that age produces in augmenting the severity of all diseases, more especially those of the skin. The propriety of separating the *local* from the *general* pruriginous affections requires no comment. No age, no sex is

exempt from the attacks of prurigo; it is observed to make its appearance in all seasons, and to find its victims in every rank of life.

1. **General Pruriginous Affections.** — When the disease assumes that mild form which Willan has denominated prurigo *mitis*, the itching is first experienced upon the shoulders, the breast, the loins, the arms, and the thighs. No papulæ appear to the naked eye; but if the finger is passed lightly over the affected parts, they are felt soft and large in the skin; as a consequence of itching, small thin black scabs are here and there conspicuous, and the cuticle between them is slightly reddened. Constant friction occasionally produces inflamed pustules, but these must always be regarded as incidental. This variety usually appears in young and otherwise healthy individuals, and commonly makes its attack in spring and summer. In the more severe form of the disease, the prurigo *formicans* of Willan, the papulæ are larger, but less obvious than in the milder variety of the disease. It affects the whole of the body except the face, the palms of the hands, and the feet; but they are chiefly seated on the loins, the back of the neck, and the thighs. The same small scabby points are also scattered over the affected parts as in prurigo *mitis*. It occurs more generally in adults than in the young, and is not more prevalent at one season than at another. The duration of both varieties is considerable, but the *formicans* is the most lasting and difficult of cure: it sometimes continues for two or more years. The pertinacity of the disease, however, is most striking in the third variety, the prurigo *senilis*, which differs from the two former only in the greater magnitude of the papulæ: this variety often continues for the remainder of life, rendering it truly wretched.

In all the varieties the itching is intolerable, augmenting in comparative severity according to the age of the patient. Thus in prurigo *mitis*, although severe, it is supportable, but it is much aggravated by sudden exposure of the naked body to the air, at the times of dressing and undressing; it is also increased by exercise and heat. In *formicans* the itching is more incessant, and often accompanied by the sensation of ants stinging the skin, whence the appellation *formicans;* but this feeling is usually more like hot needles running into the skin than the stinging of ants. In the *senilis* the itching is insupportable and more permanent than in either of the other varieties, tormenting the patient to a degree almost sufficient to cause phrenzy; but it is sometimes surpassed by the stinging in *formicans*, which often causes cramps and contractions of the extremities in a remarkable manner.

When great cleanliness is neglected in any of the varieties of prurigo, pustules and vesicles sometimes appear among the papulæ; and when the disease has been of long continuance, the skin acquires a preternatural thickness, the cuticle separates in a scaly scurf, and rhagades form. In these conditions of the surface, in dirty persons, pediculi are observed to infest the fissures of the altered cuticle. These appearances of pustules and other changes during the continuance of prurigo have led to the erroneous opinion that the milder variety may be converted into itch and impetigo. The disease may be complicated with these affections, but its conversion into them may be fairly doubted.

The *causes* of prurigo, whatever form it assumes, are obscure. Its appearance, however, is often preceded by morbid affections of the stomach, sickness, gastrodynia, cephalea; sometimes it supervenes upon particular kinds of diet, namely, salted meats, shell-fish, and even other kinds of fish, namely, mackerel, herrings, and salmon: it has also followed the free use of fermented liquors and spirits, and, occasionally, excess in the use of vinegar and condiments and pickles made with it. We have witnessed an instance of a temporary prurigo from the use of the crystallized citric acid, in the formation of the effervescing draught, although no such effect was produced when recent lemon-juice was employed. It often appears among the lower classes of society, when they are lodged in damp and ill-ventilated apartments, badly nourished and ill-clothed. It is also observed to attack most frequently persons of spare habits, with sallow complexions, subject to visceral diseases, who are reduced in strength by over-fatigue or watching, or lowered in vital energy by mental affections. But although these may be regarded as predisposing causes of prurigo, yet the condition of the nervous system that renders it morbidly excitable, and which really constitutes the disease, is still unknown. It is easy to conceive that, as age advances, the secretions must necessarily become more acrid; and this may account for the greater severity and pertinacity of the disease in old people; but as it appears in all ages, there must exist some peculiar state either of the secerning system, which supplies the acrimony that may be supposed to act on the cutaneous nerves and capillaries to produce the disease, or some altered condition of the extreme nerves that renders them more susceptible of impression from ordinary agents than in the healthy state of the system. What either of these states consists in we have yet to learn.

With respect to the *diagnostic* symptoms that enable us to recognise prurigo from other cutaneous diseases, the chief are undoubtedly the obscure, or almost invisible, character of the papulæ, and the degree of itching attending them. It might be confounded with lichen; but the papulæ are larger, softer, and less apparent than those of lichen, which also never display the minute black crusts that often appear in prurigo; and the itching in the former disease is much less both in degree and in permanence than in the latter. With itch it is not likely to be confounded by those who are familiar with the appearance of that loathsome disease. Itch is, besides, a vesicular affection, and the vesicles being acuminated and filled with a pellucid lymph can scarcely be confounded with the soft flat papulæ of prurigo: the site of scabies also differs from that of prurigo; the former occupies chiefly the fore-parts of the arms and the under part of the thighs, the spaces between the fingers and the axillæ and the flexures of the limbs; the latter, regarded as a *general affection*, has its seat mostly on the shoulders, the back, and the fore-part of the thighs. Scabies is contagious, prurigo is not communicable by contact. It is scarcely possible to confound it with ecthyma,

eczema, impetigo, or any other cutaneous eruption.

The *prognosis* in prurigo must always be uncertain as far as respects the continuance and curability of the disease, even when it assumes its mildest form. In old age and in worn-out constitutions it may be considered as incurable.

The *treatment* differs according to the variety of the disease. The mildest form, prurigo *mitis*, is benefited by a steady perseverance in the use of the tepid-bath, even when the disease is apparently for a time augmented by its employment. (*Lorry*, de Morb. Cutan. cap. iii. art. ii. par. ii.) When the bath cannot be procured, the skin should be regularly washed twice a day with warm water. We have observed much benefit to follow the daily use of the vapour-bath obtained in the manner of the Hindoos, namely, by seating the patient naked upon a chair, and after placing beside him a bucket of boiling water, enveloping his person and the apparatus within a large blanket, closely pinned round the neck, so as to prevent the escape of the hot vapour. The body should be gently rubbed by the hands of the patient whilst he remains in the bath; and when the temperature of the vapour falls, a hot brick should be dropped into the bucket to restore it. Mild soap or small quantities of the pure alkalies may be added to the water, when the body is immersed in the bath. We have not observed any advantage derived from the addition of sulphureous compounds.

In prurigo *mitis*, bleeding and active purging, followed by the internal use of sulphur and carbonate of soda or of nitre, have appeared to mitigate the itching, particularly in young and otherwise healthy subjects. If saline purgatives be employed, they should be combined with either the diluted sulphuric or the nitric acid. In prurigo *formicans* the same general means are necessary, with the addition of light tonics, such as decoction of sarsaparilla or serpentaria, or the solution of sulphate of quinia with the addition of diluted sulphuric or nitro-muriatic acid in doses of a fluidrachm, if the constitution of the patient be enfeebled or naturally weak. No benefit results from courses either of purgatives or diaphoretics.

We have little to propose respecting the general treatment of prurigo *senilis*. In most instances, the disease seems connected with a worn-out languid state of the habit, and requires the aid of a chalybeate, either natural or artificial; we prefer the former, but when it cannot be obtained, we consider the solution of the hydriodate of iron, in small doses largely diluted, as the best substitute. Some benefit has occasionally been derived from the Harrogate waters, employed internally and externally at the same time. When the itching is very severe, the warm-bath affords a temporary alleviation, and the warm sea-water bath should always be preferred to the fresh-water bath when it can be procured. When neither can be readily obtained, much benefit has followed the employment of a lotion of the bitter almond emulsion, containing one grain of the bichloride of mercury in each fluidounce of the emulsion, and one fluidrachm of hydrocyanic acid. When pediculi infest the skin, the most effectual mode of destroying them is the fumigation with cinnabar, which acts promptly and effectually; or, where this is objected to, an embrocation with one part of the oil of bitter almonds, one part of the oil of turpentine, and six parts of olive oil, will be found useful: the fumigation, however, is more decidedly useful than the embrocation, as it not only destroys the living insects, but their ova, which often escape the action of the embrocation as they lie in the rhagades.

2. **The local pruriginous affections** require a separate notice, as they have scarcely any affinity with the general diseases which we have just described. Two of them, namely prurigo *præputii* and *urethralis*, are objects rather of surgical than of medical treatment, and therefore do not require to be noticed here; and a third, prurigo *pubis*, arising solely from the presence of pediculi, is cured by whatever destroys the insects that cause it. The ointment of the white precipitate of mercury of the pharmacopœia, or an ointment made with equal parts of mercurial and sulphur ointment, answers every indication.

Prurigo podicis is sometimes a very troublesome and very obstinate disease. It generally occurs in aged persons and those of sedentary habits; and although it sometimes depends on hemorrhoids, chronic inflammation of the rectum, or ascarides, yet it appears independently of those local diseases. The itching is intense round the anus and along the perineum, extending to the scrotum, which often appears changed in colour and consistence, becoming brown, thick, and scaly. The irritation increases at night, and varies greatly, according to the diet of the patient.

Prurigo *podicis* requires a different treatment according to the degree of irritation and the habit of the patient. When it is severe, and there either exist hemorrhoids or a tendency to them, local bleeding is necessary; and this is best accomplished by cupping over the sacrum. Emollient cataplasms, composed of bread soaked in a strong decoction of poppy-heads in vinegar and water, also afford much relief to the itching at night. Rayer recommends the gelatino-sulphureous lotions proposed by M. Dupuytren, especially when the parts are excoriated by friction. We have no experience of this application, and would rely more on local bleeding, and the zinc or diluted tar-ointment; or on an ointment composed of ℥ss of acetate of lead, ℈i of sulphate of zinc, f℥iv of tincture of opium, and ℥iss of lard. We have seen much comfort derived from the daily employment of the warm hip-bath at bedtime, and the cold hip-bath in the morning. Little internal medicine is requisite: the secretions should be improved by the administration of very minute doses of calomel, namely, one-sixth of a grain combined with three grains of extract of conium at bedtime, and half a drachm of the solution of ioduret of iron, equal to gr. iss of the salt, in a large glass-full of water twice a day. In old worn-out habits, the fluid extract of sarsaparilla, in doses of a table-spoonful in half a pint of milk three times a day, has proved useful. But it must be acknowledged that this troublesome affection often resists every treatment that has been suggested.

Prurigo scroti resembles prurigo *podicis* in many particulars, and seems to originate in similar conditions of the habit. It requires nearly the

same treatment. Lotions made with calomel or bichloride of mercury and lime-water, without being filtered, have been found useful. When the disease arises in plethoric individuals from violent exercise in hot weather, nothing more is necessary than daily ablutions with tepid soap and water, regulating the bowels, and avoiding stimulant diet.

Prurigo muliebris differs little from the last-mentioned varieties, except as regards the nature of the parts affected and the sex of the patients. It is frequently connected with leucorrhœa, especially when it appears after the cessation of the catamenia. In some instances the itching and irritation about the labia and os vagina is so intolerable as to drive the patients from society, and sometimes to excite a degree of nymphomania. In such cases leeches to the vulva, and cooling saturnine emollient and narcotic lotions are indicated. On the continent much confidence is reposed on bleeding in the feet or ankles, but we are of opinion that more benefit is derived from relieving the affected parts than by any revulsive measures. Whatever local applications are employed should be frequently changed, and thus the following may be alternately used; the ordinary black-wash; the orange-wash, composed of two grains of bichloride of mercury and a fluidounce of lime-water; equal parts of the solution of the chloride of soda of Labarraque and water; and a lotion composed of two fluidrachms of liquor potassæ, a fluidrachm of hydrocyanic acid, and eight fluidounces of bitter-almond emulsion. In one very obstinate case, the writer of this article found much benefit from pencilling the affected parts with a solution of nitrate of silver, in the proportion of two grains of the nitrate to a fluidounce of distilled water, acidulated with two minims of diluted nitric acid.

It is scarcely necessary to remark that, in every local pruriginous affection, much heat should be avoided, and a firm mattress instead of a feather-bed, adopted. As the irritation is always most severe in the night, much comfort may be procured at that time by applying the sedative lotions cooled in ice. If possible, friction of every kind ought to be avoided. It is also of importance to refrain from the use of all seasoned food, aromatics, coffee, wine, and fermented and alcoholic liquors, during the continuance of the disease.

A. T. Thomson.

PSEUDO-MORBID APPEARANCES.—There are three conditions in which any tissue or organ of the body may be found, between which it is necessary to discriminate with accuracy, in order to form correct inferences in morbid anatomy. The first of these is the natural or healthy, which we find to present certain varieties either of colour or density, according to the age of the subject. The second is the abnormal or morbid, and is to be regarded as the result either of some perversion of the development of a part, or of the influence of disease upon it. The evidence of this condition is derived in the one case from some congenital malformation, and in the other from certain appearances which the texture of the part exhibits, and which vary in aspect and extent, according to the duration and violence of the disease: these are the morbid appearances. The third condition differs from both of those above-mentioned, yet in some points resembles the morbid. This condition is in general produced by causes which come into operation after death; sometimes, however, they may partially take effect a short time before death; and sometimes it may owe its rise to other causes, hereafter to be noticed, and only in action during life. The appearances which characterize this condition of the tissues of the human body may be denominated *pseudo-morbid appearances*, as being liable to be confounded with and as it were simulating those which are morbid.

Although the attention of pathologists has been a good deal directed to this subject of late years, we find but little written upon it, and the term pseudo-morbid in limited use. Dr. Yelloly, in a paper published in the fourth volume of the Medico-Chirurgical Transactions, was the first to point out that the mucous membrane of the stomach may exhibit an increased degree of vascularity under certain circumstances, independently of inflammatory action. In France, the extravagant assertions of Broussais, who, in order to establish a favourite hypothesis, pronounced every increase of redness to be indicative of inflammation, had the good effect of inducing anatomists to inquire whether other causes than disease could similarly alter the aspect of the tissues. By the researches of Trousseau and Rigot, (Archives Gén. de Méd. October and November 1826, and July 1827,) and also of M. Billard, (De la Memb. Muqueuse Gastro-intestinale,)—[see, also, Devergie, *Med. Lég.* 2d edit. i. 288, Paris, 1840,]—much light has been thrown upon the post-mortem changes which occur in the body, and which give rise to appearances often very similar to those of inflammation. We are likewise indebted to John Hunter, Allan Burns, and more recently to Dr. Carswell and Orfila for much interesting and valuable matter, which we shall presently have occasion to notice.*

It may be well to state our reasons for the adoption of a hybrid term, *pseudo-morbid*, in preference to others more generally in use. Let it be observed that we employ the term in question to denote those appearances in any given tissue which might be mistaken for the effects of morbid action in that tissue. To apply the terms *cadaveric* or *post-mortem* to such phenomena would be to limit their number and causes; whereas it will appear in the sequel that some tissues of the body may present appearances which must be regarded as *pseudo-morbid*, and which result from the action of causes operating *before* death. We are not aware that the term is employed by any writer except the author of an analysis of MM. Trousseau and Rigot's papers above-mentioned, which is to be found in the twenty-eighth volume of the Edinburgh Medical and Surgical Journal, and Dr. Christison, in his very valuable and elaborate work on Poisons. Under this denomina-

* Although distinct treatises on this subject are rare, we must not omit to state that it has received due attention in several modern works, either on morbid anatomy in general, or on particular parts of it. We need hardly refer to Andral's invaluable Treatise on Pathological Anatomy. In Laennec's work, also, and in those of Bertin and Hodgson, constant allusion is made to appearances supposed to be cadaveric or produced in the agony of death.

tion, then, we would be understood to include all appearances in the dead body which might be mistaken for morbid appearances, whether they arise from the action of causes antecedent to death, or whether they be strictly such as are now generally spoken of as *cadaveric* or *post-mortem* appearances.

In the great majority of cases, a more or less gradual diminution of the vital powers precedes dissolution. The influence of life in preserving the integrity of the membranes of the body, whether it act through the nervous system or in any other way, gradually diminishes, and a corresponding change is manifested. This is most conspicuous in the capillary circulation, which becomes impeded to a variable extent in several places, the vessels being less capable of resisting the force of gravitation. This disturbance of the capillary circulation may be noticed in almost every tissue in the body. In the agony of death, the same cause, it is natural to expect, will operate to a greater degree, and at the same time the occasional muscular contractions, which often mark the final struggle, must mechanically cause irregular distributions of the blood in the sanguiferous system. The extent to which these irregularities take place is in general proportionate to the strength of the patient (inversely), to the duration of the struggle, and in some cases, we conceive, to the degree of fluidity of the blood itself (directly). Any one who has ever watched a patient in the last stage of typhus fever will not want further testimony in favour of the accuracy of the preceding statements. The general cutaneous *hyperæmia* of the back and dependent parts indicates that the laws of gravitation have begun to operate to a much greater extent than during the state of health. (See an interesting essay by Bourdon, entitled "De l'Influence du Pesanteur sur quelques Phenomênes de la Vie." Paris, 1823.) We may also adduce the *pneumonie des agonnisans* of M. Laennec, the *engouement de position* of Andral, or the *pneumonie hypostatique* of Piorry, as additional corroborative evidence.

But even when life is in full vigour, local sanguineous determinations may occur independently of the immediate operation of disease on the part in which they appear. Thus the performance of peculiar functions may cause an afflux of blood to the particular organs; as for example, while the function of digestion is going on, we find that a marked change is produced in the colour of the mucous membrane of the stomach. Again, if any obstacle occur to the free return of the venous blood, there is in general formed a congestion of the capillary system to a greater or less extent; this is more conspicuous where the veins are destitute of valves, as in the mesenteric veins, the pulmonary veins. Hepatic disease, by compressing one or more ramifications of the vena portæ, and some forms of disease of the heart, are very frequent causes of the local determinations to which we allude.

With the cessation of life is removed all opposition to the full scope and play of gravitation and chemical affinities, the former of which was partially in operation during life. The manner in which the fluids seek the dependent parts is clearly to be attributed to the action of gravitation. In fact it has been proved to be so caused, over and over again, by the simple experiment of turning the body occasionally, so as to change the dependent parts; in this case the blood is invariably found to leave the vessels that were before lowest to seek those that now are so. Bodies being usually placed supine after death, the integuments on their posterior surfaces are uniformly found congested, but if the body be placed immediately after death on the face and abdomen, a similar congestion will present itself in the integuments covering those parts.

The effects produced by the operation of chemical affinities are apparent in the alterations in the texture, the density, and the specific gravities of the tissues: gases are evolved, new fluids are formed, and the membranes are often considerably discoloured; in short, in the action of these affinities consists the putrefactive process, whereby new compounds are formed, and the former constituents of the body almost wholly vanish. We find considerable variation in the period of commencement and rapidity of course of this process, not only as regards different bodies compared with each other, but also with respect to particular parts of the same body. The age and habit of the individual, the quantity of the fluids, the kind of death, as well as the circumstances which preceded it, the season of the year, climate, state of the atmosphere, are so many circumstances which exert a powerful influence on the rapidity of the phenomena of this process, as must be familiar to every one who has studied anatomy even in the most superficial manner.

To the action of these same chemical affinities, we think, may be fairly attributed, at least in part, a very evident cadaveric phenomenon; namely, that increased porosity of the membranes by which the contained fluids are allowed to transude through the coats of the canals or sacs which hold them. We say *increased* porosity, for it must be admitted as the result of recent experiments, that transudation may take place to a slight degree even during life. (See the experiments of Foderé on absorption; of Dutrochet; and the Observations of Bouillaud on Dropsies.) Life, then, must be supposed to operate in limiting this porosity, by preventing the action of the chemical affinities; when life ceases, these affinities come into play, and there takes place a separation of the molecules of the tissues to a degree proportionate to the extent of action of the same affinities. There is no part of the body in which we do not observe this phenomenon; it is not confined to sacs with simple parietes, but extends also to those of which the walls are compound; we observe it to take place through the coats of vessels, through the walls of any or all of the membranous viscera, and even through serous membranes.

The alterations which are produced, then, on the several organs or membranes of the body by the action of the agencies above detailed, may be stated in general to be—1. such as affect the colour of parts; 2. such as alter their density or consistence; 3. such as alter the contents of a natural cavity, as for example a serous sac, by increasing or diminishing the quantity, or altering the nature of fluid in it.

We proceed to consider these effects as they

manifest themselves in the different parts of the body, and we shall adopt the order usually followed in making a post-mortem examination, commencing with the external integument and the cellular tissue, then proceeding to the contents of each of the three great cavities, head, thorax, abdomen; and, finally, to the arterial and venous tissues.

1. **The external Integument.**—The alterations in colour which the skin presents after death, are almost the only phenomena which it exhibits liable to be mistaken for those of disease; and even they are so distinct in the mode of their formation, that any mistake must arise from a very superficial examination. Spots of various degrees of redness, and also varying in extent, are almost uniformly observable on the dead body. In general they are of a dark red, which increases in depth of colour with the length of time that has elapsed from the death of the subject. As this cutaneous discoloration is principally owing to the influence of gravitation, we find it uniformly on the most dependent parts, the occipital portion of the scalp, the posterior surface of the neck, the back, nates, posterior parts of the thighs and legs. That it is confined to the skin may be seen by cutting into the corion where the redness exists. It is moreover to be observed that this redness is vascular, and that the surface of the skin presents the appearance of a ramiform distribution of vessels. This is important, as characterizing the kind of discoloration arising from gravitation, and distinguishing it from that which may be the result of the pressure of ligatures or vestments, &c. on the surface before death; for in this latter the redness will be found to be diffused and uniform, without any appearance of vessels.

But cutaneous discolorations or lividities may occur in situations not dependent, and at a more advanced period after death, being phenomena purely cadaveric. When decomposition has fully set in, and gases are being disengaged in the stomach and intestines, the surface of the skin of the face and neck becomes of a livid colour; the superficial veins are full, and streaks of a dark colour indicate the course of most of them. This congestion Chaussier attempted to explain by attributing it to the compression of the right auricle of the heart by the diaphragm, which was pushed up by the stomach distended with gas; and he states that by producing a similar distension of the stomach artificially, viz. by the introduction of a fermenting mixture into it, he was enabled to exhibit similar effects on the cutaneous capillary system. The compressed right auricle causes in the blood a retrograde motion from venous trunks to branches, from the branches to the capillaries, which is the more easily done, as at this period the blood has to a considerable degree resumed its fluidity. To this fermentation and gaseous development may be attributable, as Chaussier further observes, the passage of pieces of food from the stomach into the pharynx, larynx, and bronchi, the passage of worms into the bronchi, nasal fossæ or mouth. (*Chaussier*, Médecine Légale, and Table des Phénomènes Cadavériques.)

2. **The Cellular Tissue.**—The subcutaneous cellular tissue is generally more or less discoloured in the neighbourhood of or immediately beneath the cutaneous discoloration. Here, however, the change of colour takes place from a two-fold cause,—the gravitation of the fluids in the vessels, as well as the transudation of the serous portion of the blood through the vascular parietes. These two causes generally reduce the subcutaneous tissue to an anasarcous condition, which of course increases with the progress of decomposition; the serous portion of the blood, too, becomes more and more tinged by the colouring matter. We need hardly refer to the common appearance of the cellular membrane under the integuments of the back, with which every student of anatomy is familiar, in proof that this is the ordinary condition of that membrane, and that too within a very short period after death, as the effect of gravitation and transudation. But as putrefaction advances, and the blood resumes its fluidity, we observe ecchymoses to form in the subcutaneous tissue, the distinction of which from the effects of contusions before death is sometimes an important task for the medical jurist, and is rendered more difficult by the fact that these ecchymoses do not seem to be formed under the influence of gravitation, being found even in elevated parts. Although it does not strictly come within the range of this article, it may be proper to mention that the following circumstances, noticed by Orfila, will assist in distinguishing these cadaveric ecchymoses from such as may have been formed by violence or otherwise before death:—1. Their situation, which will generally be found in those localities where the cellular tissue is very lax and distensible, as in the occiput, loins, eyelids, and scrotum; 2. the general evidence of an advanced stage of putrefaction presented by the dissolving condition of all parts of the body; 3. the uniformity of colour presented by these ecchymoses, which is not usually observed in those made during life. (*Orfila*, Leçons de Médecine Légale.)

Subcutaneous ecchymoses, however, may be produced by direct violence applied to the body shortly *after* death, as has been proved by experiment by Dr. Christison, and as may often be seen in the dissecting-rooms. Effusions of blood into the intermuscular cellular tissue, it is important to bear in mind, may likewise be produced by violence to the body after death. During the winter 1830–31, we had occasion to notice this fact upon bodies which, from the then imperfect state of the laws regarding dissection, were conveyed to London tightly packed in boxes from distant parts of the country. In such bodies extensive extravasations of blood into the cellular membrane between the muscles of the back were uniformly present. This fact had been likewise previously well ascertained by the happily devised experiments of Dr. Christison on the occasion of the murders committed at Edinburgh. (Ed. Med. and Surg. Journal, vol. xxxi. p. 243.)

We do not find any induration of the cellular tissue of a pseudo-morbid character; but it may be remarked, although the fact cannot have escaped the most superficial observer, as a post-mortem result, that this tissue is frequently emphysematous, and, indeed, always so after a certain period in the work of decomposition, but sometimes very soon after death, as in some low and putrid fevers, &c.

3. **The Head.**—On opening the cranium, the attention is first directed to the quantity of blood contained in the small venous trunks which are seen ramifying on the surface of the dura mater and in the sinuses. It was long ago noticed by Vicq d'Azyr, and subsequently by Marc, that the straight sinus and torcular Herophili uniformly contain coagulated blood, in consequence of the blood when fluid flowing to that dependent position. On the same principle we may expect to find the superficial veins of the dura mater more distended towards the posterior portion of that membrane. With respect to the general appearance of the dura mater, the anatomist has only to take care that he attributes a condition of hyperæmia of it, whether local or general, to its proper cause: in consequence of the fibrous character of this membrane, it is not liable to a diffuse discoloration, such as some of the other tissues are, nor do we find any alterations of its consistence which are at all likely to be mistaken for morbid ones. In fact it resists the putrefactive process for a considerable time, as do all membranes of the same nature. It is proper, however, to remember that a *hyperæmia* of this membrane may be developed in the progress to decomposition, by the disengagement of gas in the stomach, and the compression of the right auricle, in the same manner as Professor Chaussier supposed some cutaneous lividities to be produced, as already alluded to.

When the dura mater, with its adherent layer of arachnoid, has been slit up, so as to expose the visceral layer of the latter membrane, and in fact to open into the arachnoid sac, the anatomist generally looks first for some effusion between this membrane and the subjacent pia mater. We fear that in general too much stress is laid upon the occurrence of effusions between the arachnoid and pia mater. Hence what is really a natural condition is very apt to be mistaken for a morbid one; and, on the other hand, the total absence of effusion is too often regarded as indicating a state of health, when such a conclusion can be by no means constantly deduced. The interesting discoveries of M. Magendie relating to what he has termed the cephalo-spinal fluid, deserve more attention than seems to have been bestowed upon them by most practical pathologists. The principal conclusions at which he has arrived are the following:—1. That in the state of health there exists a fluid between the visceral layer of the arachnoid and the pia mater, both of the head and spine; the quantity of which is never below two ounces in the adult, and often amounts to five in subjects of large stature, and whose cranium is not of small dimensions;—that the fluid contained in the spine communicates with that in the head, and vice versâ, so as to pass freely from one cavity to the other;—and that a portion of the same fluid is found in the lateral, the third and fourth ventricles of the brain, which communicate with the space between the arachnoid and pia mater by an opening situated at the inferior extremity of the fourth ventricle, between the upper part of the spinal marrow and the valve of Vieussens. 2. That this fluid may be demonstrated in full quantity either during life, or at a short time after death; but after a period of little more than twenty-four hours it becomes absorbed, and therefore diminished in quantity, or altogether removed: if after that period sub-arachnoid effusion of this kind exist, it is to be considered either as entirely a post-mortem appearance, or the remains of the natural effusion, to which had been added a quantity of fluid, the result of morbid action. 3. That a diminution as well as an increase in the quantity of this fluid is capable of producing serious disturbance in the functions of these important portions of the nervous system. It is plain, therefore, from the above abstract of Magendie's discoveries respecting this cephalo-spinal fluid, that it would be always difficult, and often impossible, to decide whether a sub-arachnoid effusion be a natural, a morbid, or pseudo-morbid phenomenon. Unless the effusion be very considerable, and have been found very shortly after death, we cannot with certainty pronounce it to be the effect of disease. But those which are found forty-eight or seventy-two hours after death are for the most part pseudo-morbid, being caused by the transudation of the serous part of the blood through the vascular parietes, so much so that, in opening a body two or three days after death, we may invariably expect to find sub-arachnoid effusion to a greater or less extent. We conceive that a due attention to these facts connected with the cephalo-spinal fluids will sufficiently account for the surprise or disappointment which some have expressed respecting the want of coincidence between the severity of symptoms and the extent of effusion.

The degree of colour of the pia mater is often increased by the same causes which we have already enumerated as influencing post-mortem sanguineous determinations; in this case it will always be found that the other tissues within the cranium which admit red blood are similarly congested. In some cases this congestion may go so far as to produce extravasation; and if the body has lain long after death, the serum effused between the pia mater and arachnoid will be more or less tinged with the red particles of the blood. We may here remark further, that sanguineous extravasations from apoplexy, if extending into the cavity of the ventricles, will communicate their colour to the cephalo-spinal fluid, provided the natural communication of the internal cavity of the brain with the sub-arachnoid cavity be not interrupted.

With respect to the encephalon itself, it may be stated that in general (such obvious cases as apoplectic clots, abscesses or tumours being excepted) it is extremely difficult, nay, often impossible, to decide between the morbid and pseudo-morbid states of this organ. This latter state is such as manifests itself by a change in the colour and consistence of the cerebral tissue. As to colour, we find it, here as elsewhere, influenced by the quantity of fluid blood in the viscus: in the cortical substance, from its much greater vascularity, that discoloration is most likely to appear; and it is of the first moment to distinguish it from the redness of inflammation, because we find that the same colour may be the result of an active determination of blood to the brain, as well as arise from a mechanical congestion of its membranes and substance. To determine this question it will be necessary to note accurately certain collateral circumstances — the condition of the arterial and venous system of the head generally—the degree

of plentitude or vacuity of the heart, whether it afford any obstacle to the free return of the blood, or by an increase in its propelling power magnify the momentum of the columns of blood to the head—the position in which the head of the individual has been laid since death—and also whether putrefaction has begun, or the degree to which it has advanced.

The alteration in consistence, by a diminution of it, (*softening*,) is the most constant and obvious change which the brain and spinal marrow present. This softening is equally the result of disease and of the tendency to decomposition. Before proceeding to indicate the distinctions between these two kinds of softening, it may be well to notice that in the state of health different parts of the cerebro-spinal axis present a marked difference as to consistence. Thus, in the adult, the spinal marrow is softer than either the cerebellum or cerebrum; the cerebellum than the brain; both these parts softer than the pons Varolii. In the child the spinal marrow is firmer than the brain, and more resisting than in the adult.*

The morbid and pseudo-morbid softenings present many characters in common, as to situation, colour, smell: indeed, we have no sign sufficiently free from ambiguity to indicate either of these conditions with certainty: both attack the grey substance most frequently, and before the white; both exhibit the same varieties and shades of colour —with this exception, that in the morbid softening we often see the affected part of a bloody tinge, arising from a slight sanguineous effusion: sometimes a purulent infiltration is found, which is obviously decisive. In the extent of these two forms of ramollissement, we have a more certain indication of their cause; the pseudo-morbid will generally be found to pervade the whole cerebral mass, varying perhaps in degree according to the above-mentioned scale of natural variations of consistence, but the morbid ramollissement is almost invariably circumscribed. We say *almost*, because a morbid ramollissement has been met with of unusual extent, occasionally in the adult, but more frequently in the new-born infant. A state of general ramollissement of the brain is met with in cases of general anasarca, and differing very much from morbid softening. It arises from the infiltration of the brain by the fluid effused in the cranium and beneath the arachnoid. It can be produced in the dead body by injecting water through a small opening made in the head; the whole fluid injected will not be found in the serous membrane. (*Gendrin*, Hist. Anat. des Inflammations, vol. i. p. 188.)

M. Orfila suggests the propriety of pronouncing with caution on a morbid ramollissement merely from its locality being defined, because the cadaveric softening does not begin at the same time in all parts; the fornix, septum lucidum, and walls of the lateral ventricles, being the situations in which it first shows itself.

The spinal marrow is remarkable for the rapidity with which it softens. Every anatomist knows that in order to dissect that organ satisfactorily he must obtain it from a body quite recently dead, and that even then a short exposure to the air causes a rapid diminution in its consistence. The internal grey substance seems more prone to this diminution of consistence than even the white, and hence the great diversity of opinion among anatomists respecting its exact form and characters in a state of health. However, in this organ there does not appear, so far as we at present know of its morbid states, any difficulty in distinguishing the pseudo-morbid softening from that which is caused by disease; for the circumscribed locality of the latter, with the augmented vascularity of the surrounding portion, and slight sanguine tint of the softened part, will in general be sufficiently characteristic. We are not aware that such a decidedly pathological general ramollissement of the cord has been found as we have noticed in the brain.

4. **The Thorax.**—On opening the chest in the usual way, the membrane of the pleura first attracts notice. After the lapse of some time from death, an effusion is invariably found in this serous sac, which is liable to be mistaken for a morbid one. The subserous cellular tissue and the pulmonary substance being abundantly pervaded by fluids, it follows that a transudation of them must necessarily occur after a certain period, and of course they will be collected into the sac of the pleura. The bloody colour of this fluid, its serous character, the absence of any organizable matter such as serous membranes are prone to secrete, are sufficient to prove that this is not a morbid phenomenon; moreover, it will seldom be found except in a body examined at least forty-eight hours after death, and its quantity will be in proportion to the condition of the body as to decomposition. Sometimes, but rarely, gaseous effusions take place in the pleural sac; they are in general complicated with old pleuritic effusions, and result from their decomposition, thus constituting one of the species of pneumothorax described by Laennec. Whether this disengagement of gas takes place before or after death is not easily determined; probability is in favour of the latter, but the experiments of Gendrin seem to indicate the presence of a variable quantity of gas in the chest in very acute pleurisies, appearing just when the inflammation seems to have arrived at a certain degree of violence.

In the mucous membrane which lines the air-passages, from the larynx and trachea to the minutest bronchial ramification, discolorations occur from various causes, which are extremely likely to deceive even a practised eye. In the larynx, trachea, and larger bronchi, this discoloration is not so variable. We here find a passive hyperæmia from the gravitation of the blood, in which case the mucous membrane is only partially congested. We also find here a congestion from obstruction to the circulation generally, dependent on disease of the heart; but in the minute bronchial ramifications we find not only the influence of gravitation or transudation after death producing alterations in the aspect of the membrane, but likewise these causes are apt to take effect in the

* *Orfila*, Exhumations Juridiques, tom. ii. p. 225. Such is undoubtedly the case at the usual period after death when post-mortem examinations are made. But we are disposed to think with Calmeil, that immediately after dissolution the spinal marrow is of firmer consistence than the brain. The Essays of this author on the Anatomy and Physiology of the Spinal Marrow are well worthy the reader's attention. Vid. Journal de Progrès des Sciences Méd. tom. xxxi.

struggle of death, or even some time before death in very debilitated persons. The progress of putrefaction in general produces a very marked and diffuse brown colour of the mucous membrane, much more intense in the smaller tubes. To be able to decide upon any one of the above species of hyperæmia of the bronchial membrane will require a careful consideration of coexisting circumstances. In the latter instance the general condition of the pulmonary and the other tissues as to their state of preservation, will materially assist; in the other cases the injection is ramiform, and the membrane does not appear so uniformly dyed, the redness being chiefly limited to dependent parts; and the state of the heart or great vessels will assist further in deciding upon the true nature of the redness. These circumstances will direct us in discriminating any of these different forms of redness not only from the others, but also from that which is produced by inflammation. Inflammatory redness, it should be remembered, is often accompanied with some secretion, either a viscid and adherent mucus, or a pseudo-membranous exudation, or even purulent fluid, all which are unequivocal proofs of the morbid nature of the colour of the membrane.

In examining the pulmonary tissue itself, we experience considerable difficulty in distinguishing between its pseudo-morbid and morbid conditions. We can say with confidence, from tolerably extensive opportunities for studying the subject, that there is no one point in morbid anatomy more difficult to pronounce upon with certainty, than whether a hyperæmia of the lung be inflammatory or not. Every one must have experienced how unsatisfactory are the signs of the second stage of pneumomia — the *engouement* of authors. It is obvious that this difficulty is greater the longer the period which may have elapsed since the death of the subject. It however rarely happens that a patient dies in the first stage of pneumonia; most frequently we find that the disease has in one portion of the lung advanced to its second stage (*red hepatization*), and very frequently the third stage (*grey hepatization*) is exhibited in the same lung along with the two preceding. Where either of the forms of hepatization exists, there can be little doubt as to the nature of the congestion in any other part of the lung. Moreover, we may remark that the inflammatory congestion affects the upper as well as the dependent parts. The following observations from Andral will show how he estimated the difficulty of laying down any distinction between inflammatory and the pseudo-morbid hyperæmia. "It is," he says, "in the lungs as in the intestines, where a local accumulation of blood may be found in the dead body, which has had no share in producing any of the morbid phenomena observed during life; but was formed during the last moments of existence, or after life ceased altogether. Hence it follows that the existence of a simple congestion, especially when it occupies the most dependent portions of the lung, is not sufficient to prove that a process of irritation or inflammation had been going on there during life. Does an alteration in the consistence of the part afford a more certain criterion to judge by in such cases? For a long time I was of opinion that when the lung was red and gorged with blood at its posterior portion, and at the same time was softer and more easily broken down than natural, it was a proof that the hyperæmia was caused by inflammation; but I have since altered my opinion, and am now convinced that whenever the sanguineous congestion is so great that the lung contains a larger proportion of blood than of air, the pulmonary parenchyma is invariably soft and friable. The reason of this fact will readily be understood if we reflect that, when the lung contains a much larger proportion of air than of blood, the parietes of the bronchi, when pressed by the finger, press in their turn on the compressible fluid they contain, and in this way, by compressing or expelling the air, retire before the pressure of the finger, and so escape being ruptured. But when the lung contains a larger proportion of blood than of air, the former fluid being almost wholly incompressible, the pulmonary tissue cannot recede from under the finger, and is therefore easily ruptured." (Andral's Pathol. Anatomy, by Townsend, vol. ii. p. 508.) And in another section he remarks, "as the anatomical characters of the hyperæmia are precisely the same in both these cases, it follows that, in this instance at least, the true nature of the lesions found on dissection can only be known by the nature of the symptoms observed during life." (Op. cit. vol. ii. p. 509.)

We can hardly suppose it possible that gangrene of the lung and any post-mortem congestion of it could be confounded together. The peculiar smell from a gangrenous spot is a certain indication of its true nature. However, if any condition do appear closely to resemble gangrene, by carefully washing the suspected portion of lung in clean water we shall in general succeed in exhibiting the sound pulmonary texture.

In the pericardium the signs of disease are so very obvious that we know of no phenomenon which that membrane can present which could be considered pseudo-morbid. There is found, however, in its cavity, after a certain time, a sero-sanguinolent effusion in small quantity, which, like a similar one above noticed in the pleura, is to be regarded as a cadaveric result. (See HYDRO-PERICARDIUM.)

Except after the lapse of a considerable time from death, we have never seen any post-mortem condition of the substance of the heart which could be mistaken for a morbid one. We not uncommonly meet with softening of the muscular texture of the heart; and this may arise from so many different causes, that Andral has enumerated six varieties of it; with any of these may be confounded a true cadaveric softening, which, however, generally does not appear for a long time after death. The best criterion of the true nature of a softening of the heart's parietes may be formed from the state of the internal membrane; if that membrane be healthy, or do not partake in the diminished consistency of the heart's parietes, then the great probability is in favour of this condition being the result of disease. But when the internal membrane is of a deep red colour, and is more or less softened, while at the same time there is no appearance of any lymph or other product usually resulting from inflammatory action, then we consider it impossible to determine with

certainty to what cause the softening is to be attributed. In some instances the blood has been known to transude through the walls of the heart, and form ecchymoses either between the fibres or on the external surface. Such ecchymoses will want the regularity of form which those formed during life would possess, and rarely, if ever, take place except in an advanced stage of decomposition. We have twice seen numerous ecchymosed spots on the hearts of patients who died of purpura hemorrhagica; but these should be considered as morbid, and attributable to the same cause as the cutaneous ecchymoses.

The internal membrane of the heart often presents an obviously pseudo-morbid alteration in its colour. When the examination of a body does not take place for forty-eight hours after death, or in very warm weather for a longer period, we may invariably expect to find this membrane of a red colour to a greater or less extent. That portion which lines the dependent parts of the cavities will always be found so, and to a greater degree than the rest, because the colouring matter sinks through the coagulum so as to come immediately in contact with the internal surface of the heart; and this will account for the fact, that except at a very advanced period in the cadaveric decay, this redness generally appears in patches, and those most intense which are most dependent. A precisely similar redness will occur under circumstances which can leave no doubt that it took place during life; but as this subject is closely connected with the appearances of the internal coats of arteries, we shall defer any farther remarks upon it till we come to that section of our article.

The fibrinous masses which are almost uniformly found in the cavities of the heart are not to be considered in every instance as morbid productions, as the older pathologists thought; in general they are formed after death, or immediately before it, and merely form the natural disposition of the fibrine to assume the solid form. However, some of these coagula have been found organized, some containing pus, others with pieces of bone on them or in them; whence we must conclude that these fibrinous masses may be formed before death, and produce considerable disturbance of the circulation.*

5. **The Abdomen.**—Of all the serous membranes, the peritoneum is most liable to *morbid* effusions. But in this cavity, as well as in that of the pleura, we generally find a post-mortem effusion after thirty or forty hours; which, like that of the pleura, is in general coloured by more or less admixture of blood. This fluid will always, except it be in very great quantity, be found in the pelvic portion of the peritoneum. In the serous membrane itself, we know of no pseudo-morbid appearance likely to occur, except we name that softening produced by contact with the acid contents of a perforated stomach, which we shall presently notice more fully. The discoloration arising from contact with the gall-bladder is too evident to be mistaken for disease.

In examining the exterior of the intestinal tube as the intestines lie in the abdominal cavity, we observe appearing through the serous coat vascular ramifications more or less numerous and more or less filled with blood. Here we observe well illustrated the effects of gravitation on the blood within the vessels of the intestines; those coils which are lowest, namely those which hang into the cavity of the pelvis, always presenting the deepest colour, and also the most depending portions of all the parts of the canal.

There is no membrane of the body which presents pseudo-morbid coloration arising from so many different causes, as the gastro-intestinal mucous membrane: we speak now of the colour which results from particular distributions of the blood in its vessels. In the first place, we may notice that the *act of digestion* produces an increased degree of redness of the mucous membrane of the stomach as well as of the small intestine. The effect produced by digestion on this membrane has been well noticed by Gendrin; he says that the membrane becomes of a rosy hue, deeper in young than in old subjects; and that it is owing to the action of this function may be very well inferred from the fact that only that portion of the membrane is coloured which is in contact with the chymous mass. It is also remarked round the portions of digested matter which are found in the lower part of the small intestine. It appears, too, that the degree of colour depends very much upon the quality of the food, being less intense when the food is of a bland nature. This has been proved upon two dogs, to one of which milk only had been given, to the other an equal quantity of rich broth highly seasoned; the mucous membrane of the latter was of a deep red colour, while that of the former was very slightly altered. Fasting also has the effect of altering the colour of this membrane, giving it a rosy hue in its whole extent; in this way differing from the effects of digestion, which produces only a partial colouring.

A third cause of alteration of colour results from "the passive hyperæmia," to adopt the language of Andral, "which has always a tendency to take place in the last moments of life in the parts abounding with capillaries." In this case the colour is generally of a darker hue, and the greatest quantity of blood is found in the vessels of the depending portions of the intestines.

Any obstacle to the free return of the venous blood, whether it reside in the liver, or from compression of the vena portæ itself, or whether it is to be found in the heart, will produce increased vascular injection of the mucous membrane; the blood in such cases will be of the venous kind, and the injection extensive, and even universal; varying, however, according to the period before death at which the obstruction commenced.

Such are the circumstances which operate before death in producing pseudo-morbid colouring of the mucous membrane. In the true inflammatory redness, there is generally some degree of thickening of the membrane, as well as a viscid mucous secretion in variable quantity. The redness, too, is not affected by position, being equally great on the upper as in the depending portions, and in a more advanced stage of the inflammation there may be lymph or purulent matter.

* Dr. Harty has given a very elaborate narration of the symptoms of two cases, which in his opinion were produced by these so-called polypi of the heart. Dub. Med. Transactions, vol. i.

After death, we find the blood accumulating with greater rapidity, and in a more marked manner in the depending parts. This phenomenon may be observed as to the mode of its occurrence, by removing a coil of intestine, tying it at each extremity, and hanging it up; after some time the blood will be seen to leave the upper part, and accumulate in the lower portion of the intestine. If there be much blood in the capillary system of the mucous membrane, we observe another cadaveric phenomenon, after the body has lain for some time: the mucous membrane, and of course the villi, are gorged with blood, which presently begins to ooze out upon the surface, and to pass into the cavity of the intestine. This we lately saw well exemplified in the case of a young gentleman who died of fever, and whose body we could not obtain permission to examine till five days after death. All the upper portion of the small intestine was free from sanguine congestion, but that part of it which lay in the pelvis was found to be of a dark red hue externally; the mucous membrane being gorged, especially at its inferior part, and the cavity of the intestine full of fluid blood. This phenomenon is easily explained if we consider how freely the blood passes from the large mesenteric veins to the villi, which moreover, from the researches of Ribes, appear to contain more veins than arteries; it is also further accounted for by the great facility with which an intestine may be inflated by blowing air into its principal venous trunk. Contact with the spleen produces a redness of a different kind, being more of a uniform stain or tinge of the membranes in its vicinity. This obviously arises from transudation of the blood from this vascular body through its coats. After a certain period we find the blood to transude through the coats of the larger vessels of the stomach and intestines so as to produce a more or less continuous stain, or extravasation of blood in the cellular membrane on each side of the trajct of the vessel. This appearance must be familiar to every one who has examined a stomach in an early stage of decomposition; the stain is distinctly visible on the mucous surface, and may also be noticed on the peritoneal surface. The period at which this transudation may take place will very much depend on the season, the temperature of the room, and perhaps the state of the blood.

There are two other causes of discoloration which it is well to remember, although the appearances they produce may not be very apt to be mistaken for morbid ones. One of these is the presence of gases in the cavity, which may alter in various ways the colour of the blood collected in the coats of the intestine. The action of the bile too, by soaking into and combining with the mucous membrane, produces a very obvious change in its colour, and this may even extend into the stomach. There is a third cause of discoloration resulting from the action of the gastric acid on the blood, which we shall notice more fully after considering the other effects of that acid.

In inspecting the alimentary canal, we should not neglect to observe accurately the nature of its contents, for sometimes some coloured fluid may be found among them which may impart its colour to the membrane. Dr. Christison quotes a case in which a suspicion of poisoning had arisen from the inspector hastily referring the altered colour of the inner membrane of the stomach to inflammatory action. It was ascertained that the deceased was in the habit of taking a strong infusion of corn poppy, (*papaver rhœados,*) which, when administered to dogs, produced appearances identically the same. The inference was obvious. (Vide Christison on Poisons, p. 121.)

It will thus appear, that in attempting to form a judgment as to the precise nature of any coloration of the alimentary mucous membrane, there are numerous sources of fallacy which it is important to avoid. It is in the stomach that most of these pseudo-morbid appearances occur, but many of them likewise are to be met with in the intestines. They may be classed as follows: 1st, those which are produced antecedent to death, and 2d, those which are strictly post-mortem or cadaveric. Under the former are comprehended, 1, those produced by the stimulus of digestion; 2, those resulting from long abstinence; 3, the result of passive hyperæmia toward the close of life; 4, such as arise from a disturbed state of the circulation owing to a retardation in, or obstacle to, the free return of the venous blood. Under the cadaveric may be enumerated, 1, that arising from post-mortem hypostasis, which is sometimes accompanied with cadaveric hemorrhage; 2, that produced by contact with a vascular body like the spleen; 3, those stains or streaks resulting from transudations of the blood through the coats of the larger vessels, more especially of veins; 4, that produced by the action of gases evolved into the cavity of the intestine, upon the blood contained in its vessels; 5, that from imbibition of the bile; 6, that from contact with some coloured fluid in the intestine forming part of the ingesta; and, lastly, that produced by the action of the gastric acid, of which we have yet to speak.

Attenuation or thinning of the mucous membrane is occasionally met with as a morbid phenomenon. We sometimes, however, find it caused mechanically by a continued distension of the tube. Thus Billard relates a case in which he found a mass of lumbrici in a portion of small intestine, which was so distended by them that it almost equalled the cœcum in volume, and its wall was so thin as to permit the worms to be seen coiled up in its interior. We lately examined the body of a young girl, in which the cœcum was distended with fæces to such a degree that it extended across the upper outlet of the pelvis to the left iliac region. From the excessive attenuation of the wall of the intestine, the fæces were distinctly visible through it.

Softening of the mucous membrane is an alteration of texture which equally takes place under the influence of morbid causes as of others of a different nature. Nobody denies the existence of softening of the gastro-intestinal mucous membrane consequent upon inflammation; but it may reasonably be doubted whether it arises from that cause so frequently as has been supposed. Neither can this alteration of consistence be considered as a frequent result of the putrefactive process, for unless the membrane be exposed to air, we find that it softens slowly. Andral has

found its consistence unimpaired eight or ten days after death, and in bodies which exhibited abundant signs of advanced putrefaction. Even when exposed to the air it softens slowly, as Billard did not perceive any change till the sixth day of the exposure of a portion of mucous membrane, and in a situation where the sun's rays could exert their full influence upon it. Hence we may with reason reject putrefaction or decomposition from the list of causes of this alteration, seeing that the majority of post-mortem examinations take place within forty-eight hours after death.

To John Hunter we are indebted for the first notice of what must be considered a very important fact, viz. that in the body of an individual dead soon after digestion has commenced, the mucous membrane of the stomach, the great end especially, may be found dissolved, and even the wall of that viscus perforated, and this through the solvent power of the gastric juice, "that menstruum which the stomach itself has formed for the digestion of food." (Hunter's Animal Economy, p. 231.) Without inquiring into the grounds on which so many subsequent writers or experimenters attempted to refute or deny Hunter's hypothesis, we shall content ourselves with referring the reader to Dr. Carswell's very able paper on this subject, (see Edin. Med. and Surg. Journ. v. 34, p. 282,) in which he will find the opinions of Jæger, Laisné, Gairdner and others, fully discussed, and pass on to state the facts which appear fully to establish the original opinion of the great British physiologist. The first circumstances in favour of this opinion are those related by Hunter himself, viz. the fact of having found a solution of the stomach in two persons killed suddenly and shortly after having taken food; the frequency of the solution in fishes, which generally died of violence and with the stomach full, and in other animals killed violently and during digestion.

Spallanzani, Adams, Cooper, and Carlisle afterwards confirmed these experiments. Some failures, however, occurred in the attempts to produce this phenomenon at pleasure in animals, and hence the confidence of subsequent experimentalists was somewhat shaken. Some observations strongly corroborative of the Hunterian doctrine were published by Allan Burns; he found the stomach dissolved and perforated, and not only this, but every viscus with which the fluid that escaped from the stomach came in contact was also softened in its walls; and as a still further confirmation, he observed, on examining the body two days after his first inspection, that the solution had extended considerably. Recently Dr. Carswell, in the paper above referred to, has fully succeeded in proving that this softening takes place in healthy animals killed during digestion, and that, in whatever part of the stomach "this function was going on most actively, or an accumulation had taken place of the products of secretion, there the organic alterations had also occurred." Finally, a case has occurred to Dr. Sharpey, as related by Dr. Christison, precisely analogous to that of Mr. Burns. "On proceeding to open the body of a child for the purpose of dissecting the nerves, he remarked that the stomach was perforated and gelatinized, but the adjoining parts uninjured. He then sewed up the body in order to show the appearances to some of his friends next day. By that time the peritoneal surfaces of the spleen and left kidney were found much softened and pulpy where they lay in contact with the hole in the stomach." (Christison on Poisons, p. 127.)

Such, then, is the evidence upon which we would attribute a form of softening (and perhaps the most frequent) of the mucous membrane of the stomach, to the action of the gastric juice, and it may be added that this action may go on to produce a perforation of the wall of the stomach. The softening is generally observed at the most depending part, most commonly the great sac: here the membrane appears like jelly, yet hardly so firm. "When raised between the fingers the coats crumbled to pieces like a recent pseudo-membrane," and often the serous coat is similarly softened. The only alteration of colour in the mucous membrane is that of being rendered rather whiter than the natural hue. The perforations resulting from this cause of course vary in extent according to that of the softened tissues; we find them, therefore, of all sizes, sometimes so great as to involve a considerable portion of the stomach. The margins appear half dissolved, fringed, and generally formed of the serous membrane, and for a considerable distance round the mucous membrane is gelatinized. Moreover, as has been first noticed by Dr Carswell, the blood-vessels distributed on the softened parts and also on every part which had come into contact with the fluid, were altered in colour, so as to form brownish, brownish black, or pure black arborescences. When the fluid could not come in contact with the membrane, the vessels exhibited their natural colour. It may be stated further that the fluid found in these stomachs at once reddened litmus. In the instances of this form of perforation which have occurred in the human subject, no symptoms whatever of gastric disease were present before death, the patients having died of disease of some other organs or by violence. Thus, according to an abstract which we take from Dr. Christison's work, it has been found in women who died of convulsions after delivery, in children who died convulsed or of hydrocephalus, after death from suppuration of the brain both idiopathic and traumatic, from diseased mesenteric glands, from nervous fever, and after sudden death from fracture of the skull and hanging.

The softening of the mucous membrane thus formed is to be distinguished from that which is the result of morbid irritation during life, as well as of that produced by the introduction of irritant poisons. Cruveilhier has described a condition of this membrane in the stomach of children, which he calls "*ramollissement gélatiniforme.*" This softening, like that above described, extends to the other coats of the stomach, and even causes perforation. In short, this affection described by Cruveilhier has the strongest possible resemblance to the pseudo-morbid softening of Hunter; but the evidence adduced in favour of its morbid character is derived from certain symptoms supervening a short time before death. We know of no means whereby we can distinguish between these two alterations, except, perhaps, the dark colour of the blood contained in the vessels of the softened part,

which, if the alteration described by M. Cruveilhier were the effect of morbid irritation, would not be likely to occur. On the whole, however, we are strongly disposed to the opinion that the *ramollissement gélatiniforme* of Cruveilhier is a pseudo-morbid phenomenon, and identical with that caused by the action of the gastric juice.

In a true pathological softening there are uniformly present some additional signs of inflammation; thus, we sometimes have redness of the membrane, and generally an increased opacity and a thickening of the submucous tissue; and it may be indifferently found on all parts of the stomach, even where the gastric juice could not come in contact with it; moreover, here likewise we have not the black discoloration of the blood which is a remarkable character of the softening by the gastric juice.

The perforation which results from this softening must be distinguished from that caused by inflammation or by rupture. The existence of signs of inflammation in the serous membrane would be unequivocal evidence; but sometimes the perforation or rupture occurs at too short a time prior to death to allow of the production of peritoneal inflammation, in which case the appearance of the margin of the opening, the state of the surrounding membrane, and of the submucous tissue, will assist in forming a conclusion.

We have alluded to the effect which the gastric fluid produces when brought into contact with the blood in the vessels of the stomach. The effect is nearly similar to that produced in the case of poisoning by acetic acid, related by Orfila in the Annales d'Hygiène for July, 1831, namely, a black or brownish black discoloration of the blood, without affecting the coats of the vessels. In the instance under consideration, however, the discoloration is not so extensive as in that of poisoning by the acid, the quantity of acid in the gastric juice being so small. But we sometimes meet with a brownish black discoloration from morbid action, which may be distinguished chiefly by the fact of its occupying the villi of the membrane, and by the gradation through which the colour passes from red to brown, and from brown to black; to which we may add that the discoloration by the gastric juice is most conspicuous in the large trunks. The absence of all appearance of transudation, as well as the state of the other tissues, will sufficiently indicate that the black colour is not caused by putrefaction.

In the parenchymatous viscera of the abdomen there are no pseudo-morbid appearances worthy of notice; they are chiefly such as are produced by mechanical obstacles to the free course of the blood, or such as are caused by the operation of the principle of gravitation. In some bad states of the blood the liver and spleen have been found softened in their texture to such a degree that they almost appeared to be thus altered by putrefaction; however, in general, the effect of putrefaction is to diminish the size of those organs, while the reverse often takes place in the case to which we allude.

6. **The Blood-vessels.**—It is not uncommon to find considerable vascularity of the cellular membrane forming the external investment of arteries. The minute vessels ramifying in this tissue, called vasa vasorum, are minutely injected, and form beautiful arborescences freely anastomosing over the surface of the arterial tube. These often are produced as a mere mechanical effect, or as the result of gravitation. The alterations of colour which the internal coat of arteries exhibits deserve particular attention. Every one must have observed that if an artery be slit open, its coagulum or blood removed, and its inner coat exposed to the air, it quickly acquires a bright red colour. Again, if the blood remain fluid for some time after death, if its fibrine be less contractile than in the healthy state, the inner coat of the arteries will be generally found to be deeply coloured. In examinations made when putrefaction has fully set in, a similar colouring of the same tissue will uniformly be seen. Again, if a coagulum exist in an artery, and the colouring matter have sunk to its most depending part, that portion of the inner coat will be coloured which is in contact with the colouring matter of the clot. Finally, by inclosing some blood in an artery, and keeping it there by ligatures, we are able to produce a red colour in its internal membrane. Such are the different ways in which a red colour or stain of the inner coat of arteries may be produced, very similar to that which is the first indication of inflammatory action in it. In veins similar discolorations, and from the same causes, are observed and in them those arising *post-mortem* take place much more quickly than they do in arteries. The red colour of the inner membrane of either arteries or veins can be but little depended on as a sign of inflammation; nor, indeed, can we derive any conclusion from it at all unless it be accompanied with an albuminous exudation or other unequivocal product of inflammatory action.

In the preceding detail of the various pseudo-morbid alterations which are to be met with in the principal tissues of the body, our design was, not to exhibit to the reader the difficulties in the way of forming a correct estimate of the condition of any structure, but to convince him, and in the most practical way, of the necessity for and utility of observing great caution in deciding upon the presence or absence of disease. We shall bring this article to a close by stating a few conclusions suggested by the consideration of the subject, which may serve as useful directions in making or recording post-mortem examinations.

1. Before proceeding to examine a body, the inspector should invariably ascertain, with as much accuracy as possible, the length of time which may have elapsed since the death, and it should be noted in the record of the inspection. The neglect of this has rendered many apparently valuable cases, noted in some of our standard works, utterly inconclusive. We allude more especially to cases in which serous effusion has been found round the brain or spinal marrow. 2. The reporter of post-mortem inspections should in no case content himself with merely stating what he conceived to be the state of a tissue, as, for instance, "*that such a membrane was inflamed*," but he should be careful to note, as clearly and as concisely as may be, the appearances which presented themselves, and any concomitant circumstances calculated to unfold the true nature of those appearances, whether morbid or pseudo-morbid. This

precaution need not, however, preclude any remarks as to the impression conveyed at the time of examination, but it is obvious that it will have the advantage of recording a plain statement of facts, from which each reader may have equal means of deriving a conclusion. 3. There are some points respecting the examination of certain parts worthy of attention. In every case of suspected disease of the spinal marrow, the spinal canal should be opened before the head, in order to form an estimate of the precise quantity of fluid that may happen to be effused. The advantage of this is apparent from what we state respecting the free communication between the two portions of the cephalo-spinal fluid. The brain should not be removed from the cranium until the ventricles have been examined, that as little as possible of the fluid may escape. Of course this is only applicable where the head is opened before the spine. As to the manner of opening the head, we have generally preferred to do so by sharp and strong blows of a hammer, so as to crack the skull round, the head being supported by the other hand, and not placed upon so unyielding a fulcrum as a table or block. We have found this method preferable to that of sawing, which, we conceive, disturbs the parts more, and, unless the saw be very sharp, is always extremely tedious; not to mention the difficulty of preventing the saw from injuring the dura mater, or even the substance of the brain itself.

R. B. Todd.

PSORIASIS.—The term *psoriasis* (scaly tetter; dartre squameuse,) from ψώρα, a scab or itch, was first employed by Dr. Willan to denote a cutaneous disease, which consists essentially in a greater or less degree of inflammation of the rete mucosum and contiguous surface of the cutis; and in the secretion of an unhealthy epidermis, forming itself into scales which exfoliate, and are renewed with greater or less rapidity. The natural transpiration through the affected parts is almost completely interrupted, and its place supplied by the exuberant growth of a morbid cuticle. Psoriasis is so closely allied to lepra that some writers (*Plumbe*, On Diseases of the Skin; *Duffin*, in Edin. Med. and Sur. Journ. 1826, on Squamous Diseases.) have proposed to conjoin them under one head, which in a practical point of view would be attended with no inconvenience. Both are well-marked scaly diseases, and the difference between them consists in the more perfect circular regularity of lepra, its inflamed margin, raised scaly circumference, and usually depressed centre; while the outline of the patches of psoriasis is irregular, and their centre rather elevated than depressed. Yet the connection between the two diseases is so intimate, that we sometimes observe both forms of eruption in the same individual; spots of lepra being intermixed with the more irregular and extended patches of psoriasis.

The elementary character of psoriasis is a scaly surface with inflammation of the subjacent vascular tissue; but to these are generally superadded the formation of fissures and excoriations, discharging a thin fluid, which concretes into crusts, intermingled with or formed upon true scales; and in severe and protracted cases there also occurs overgrowth of the cutis, which acquires unnatural thickness and solidity. This affection is attended with heat and itching, which, although seldom altogether absent, become at times more intense and distressing: during the exacerbations the inflamed skin flushes with heat, and swells up into ridges like an erectile tissue.

Psoriasis varies much in the rapidity of its progress: it generally appears first in the form of small, red, shining spots which become covered with scales; and under these other scales are formed, while the first loosen and fall off. Thus the scales thicken, the spots multiply, enlarge, coalesce one with another, and form large patches. In other instances of this disease, considerable portions of the integument are affected at once, becoming rough, harsh and chopped. Psoriasis is usually preceded by languor, lassitude, and loss of appetite: and is accompanied in its early stage by more or less of febrile disturbance, which is always most strongly marked in those cases where the disease is suddenly developed. It is very often periodical in its attacks, disappearing and recurring with marked regularity at certain seasons of the year. In the case of a lady, whose leg has for many years been affected with a large patch of *psoriasis inveterata*, the disease uniformly disappears during pregnancy, leaving a pale, wrinkled surface similar to the scar of a burn.

Causes.—Psoriasis is not generally believed to be contagious; but Dr. Willan, (*Bateman*, Synopsis, p. 38,) it appears, had observed *psoriasis guttata* to occur among the children of the same school or family at the same time: and we remember to have been consulted by two ladies having this disease on their necks, who were impressed with the belief that they had received it from their female attendant. Its hereditary nature is generally admitted; and several instances in proof of this opinion are known to us. Psoriasis is more frequently seen among the lower than the upper classes of society, and oftener among females than males, occurring especially during disorder of the uterine functions, as in chlorosis and after parturition. Persons of a full habit and dark complexion are most subject to this disease; and a distinct tendency to it is indicated by a dry and husky state of the skin, with languor of the circulation. It is more especially a disease of cold climates, and its occurrence is much promoted by the keen, dry winds of spring, and the sudden alternations of temperature which take place both at that season and in autumn. Hence it has been observed to recur particularly at these periods for successive years, and to be then most aggravated; but we have known psoriasis to be most severe during the heats of summer.

Various occasional causes appear to give rise to this disease; such as chilling the stomach by large draughts of cold water while heated, (*Falconer*, Memoirs Medic. Soc. London, vol. iii,); the sudden exposure of the body to cold after violent exercise, acid and indigestible substances taken into the stomach. In children psoriasis appears sometimes to originate from the irritation of dentition; and in adults it has been observed to arise during great mental anxiety, grief, and apprehension (*Bateman*, Synopsis, p. 38,)—most probably from the influence which these states of the mind exert over the digestive organs. There is reason

to believe that both gout and urinary calculus are connected with psoriasis, not as causes, but concurring consequences of the same disordered condition of the stomach and bowels. Numerous local irritations are productive of psoriasis affecting the hands and arms, as in washerwomen, bakers, and others.

Dr. Willan* has mentioned that both *psoriasis guttata* and *psoriasis diffusa* are sometimes the sequel of *lichen* and *prurigo;* and we recollect an instance where *psoriasis inveterata* appeared to have been the consequence of *eczema rubrum*. We have observed also the disease last named degenerate under our eyes into *psoriasis guttata*.

Psoriasis has been divided by Dr. Willan into numerous species, of which only four deserve particular consideration; the rest being regarded as mere varieties, for which a brief notice will suffice.

1. **Psoriasis Guttata,** (drop-like scaly tetter.) This appears in the form of irregularly shaped spots, some no bigger than a pin's head, others nearly as large as a sixpence; which multiply, extend, and coalesce into patches, all of them covered by white glistening scales, excepting those in the face, where they appear merely as red spots, rough and slightly elevated. It is seldom attended with much inflammation of the skin. Its type is sometimes acute, at others chronic; the former is most frequent in children, in whom it occasionally overspreads nearly the whole body in a few days; the latter is usual in adults. When the progress of *psoriasis guttata* is rapid, it is always accompanied by general feverish disturbance, and in many cases preceded by muscular pains. It appears most frequently in spring, and sometimes recurs annually at that season for several successive years. This is the most common form of psoriasis, constituting, according to Rayer, (Maladies de la Peau,) three-fifths of all the cases which are met with.

2. **Psoriasis Diffusa,** (diffuse scaly tetter.) The character of this species is considerably more inflammatory than any of the others, and it is more nearly allied to impetigo and eczema; indeed Alibert has described one form of it under the name of dartre squameuse humide.† The skin affected by this eruption is much more hot, red, and tender, more frequently presents fissures and excoriations, and is much less closely covered with scales, which differ from those of the foregoing species in being occasionally of a brownish tint, more irregular in their form, and placed more edgewise on the surface. Diffuse psoriasis sometimes appears at once over a large extent, the skin becoming harsh, cracked, red, and scaly: at other times its progress can be traced from the formation of minute, elevated spots, covered with distinct scales, which after a time are connected by the inflammation of the intervening spaces; these in their turn become scaly, and the whole is at length changed into one continuous eruption. Again, in other cases, the disease appears in small separate patches, which may remain distinct, but are also apt to extend and coalesce, acquiring ultimately the characters just described. The cuticle becomes rent into fissures, which discharge a thin, serous, and sometimes bloody fluid, while the cutis, which is always more or less turgid from inflammation, at length suffers a real overgrowth. The development of this disease is usually attended with constitutional disturbance, which is afterwards maintained by the continued irritation of the inflamed skin. The heat and itching are often very troublesome, and any additional excitement from increased temperature, or the friction of the clothes, produces a distressing aggravation of the symptoms. In children this is particularly remarkable, for in them diffuse psoriasis appears in a severe form, generally from the age of two months to two years. Dr. Willan (vol. i. p. 170) was led to erect this into a distinct species (*psoriasis infantilis*) in consequence of the affection of the mucous membrane of the nostrils which usually accompanies it, and the intermixture of scaly patches with smooth shining elevations, which in the cleft of the nates often assume the appearance of moist flattened condylemata. But we have seen this occur in other squamous diseases, apparently from the mere action of heat and moisture preventing the scales from forming, and increasing the morbid turgescence of the affected spots. The disease in this altered form is more amenable to treatment, the flattened elevations yielding in general readily to the application of sulphate of copper.

When diffuse psoriasis continues its progress unabated, it either destroys the patient by the effects of cutaneous irritation, and of the accompanying morbid condition of the alimentary mucous membrane; or more frequently it degenerates into the inveterate form (*psoriasis inveterata*). But the severity of the disease is usually limited to a few months, after which it becomes greatly ameliorated or disappears altogether, again to recur during the variable weather of spring or autumn, most frequently the former, but sometimes at both seasons.

The causes of this species of psoriasis are the same as those already enumerated; but it appears oftener to originate from the application of irritating substances to the skin, and exposure to sudden alternations of temperature: hence arise the local varieties which occur in washerwomen, bakers, shoemakers, workers in metals, and cooks. The first of these is often very severe, affecting the hands, wrists, and fore-arms, particularly about the part up to which they are usually immersed in the washing-tub. It arises from the irritation of the soap, and the alternate exposure of the skin to hot water and cold air, and is most frequent in spring and winter.

The baker's itch (*psoriasis pistoria*) is confined chiefly to the back of the hand, where the skin is more tender than in the palm, and where it is exposed both to the irritation of the flour and to the strong heat of the oven. We have also observed a cutaneous affection somewhat similar on the hands of cooks, arising from exposure to the scorching heat of the fire.

* On Cutaneous Diseases, vol. i. p. 156. To the works of Dr. Willan, and of his pupil and follower Dr. Bateman, the writer of this article gladly acknowledges the heavy debt which he owes. Not to have drawn from the rich treasures left us by those distinguished physicians, would have been at once discreditable to himself and unjust to his readers.

† Maladies de la Peau, Pl. 13. Another form of the same species has been named by him *dartre squameuse orbiculaire*. Pl. 14.

3. **Psoriasis Inveterata** (inveterate scaly tetter; dartre squameuse lichénoide). This, as its name imports, is the most obstinate of all the forms of the disease, sometimes originating in the diffuse species, at other times being the consequence of *prurigo senilis* or of *eczema rubrum*. It is characterized by an exceedingly thickened state of the cuticle, which appears in firm layers of a glistening white colour, resembling the shining bark of a tree, or the skin of a dried fish; divided not into the mosaic of ichthyosis, but by transverse lines and fissures: it often encases a part or the whole of a limb, and sometimes extends over the greater part of the body, leaving unaffected a portion of the face, or perhaps the palms and soles. The edges of the divided cuticle are usually curled inwards, and these chinks open and close with the motions of the body, which in such cases are not unfrequently attended with a rustling or slight crackling noise. A quantity of thin fluid, sometimes tinged with blood, oozes from the fissures, and occasionally large portions of the thickened cuticle are detached, leaving a bright red and exceedingly tender surface, at first discharging copiously a watery liquid, and then becoming covered with a hard dry epidermis, which separates from time to time in large plates. The formation of scales and flattened crusts is so rapid in this disease, that great quantities are found every morning in the patient's bed, (*Willan*, on Cutaneous Diseases,) resembling in this respect the decline of mercurial eczema, in which, however, the appearance is produced by the drying of the serous discharge rather than the formation of true scales. When the cuticle is thus extensively and deeply diseased, the nails participate in the change, becoming thickened and brittle, frequently separating and being renewed.

4. **Psoriasis Gyrata,** (serpentine scaly tetter). This very rare species of psoriasis is chiefly remarkable for the red waving ringlet-like stripes which it presents on the back or breast of the patient; the figures on one side of the spine, or on one breast, often bearing a near resemblance to those on the other. It is unnecessary to describe minutely the fantastic shapes which it sometimes exhibits; suffice it to say that the red colour of these tortuous stripes is partly shaded by a thin covering of light branny scales, which are constantly being thrown off and renewed. It is distinguished from herpetic and impetiginous eruptions, to which it bears a remote general resemblance, by the absence of vesicles and pustules. Like other species of psoriasis, it is much influenced by the weather and the seasons of the year—subsiding in summer, and becoming more intense in spring and autumn.

Such are the great divisions of psoriasis founded on its peculiar forms and the degree of its severity, and under them, especially the diffuse species, may be ranked all the local varieties which have been described by Dr. Willan and others. The most important, and perhaps the most common of these varieties, is that which affects the palms of the hands, (*psoriasis palmaria:* dartre squameuse centrifuge): it is characterized by inflammation and thickening of the skin of the palm, with scales dispersed over the surface; and very often fissures, from which thin fluid oozes, attended with heat, itching, and sometimes considerable pain on extending the fingers. Patches of the same description appear also on the inside of the wrist and on the sides of the fingers; the nails likewise are affected in protracted cases, becoming thickened and opaque, and mouldering away or being cast off. This is often observed to be an hereditary disease, and in those disposed to it the nails usually possess an unnatural brittleness which makes them snap under the scissors. In such individuals the exposure of the hands to a cold dry wind, or frequently moistening them, is almost sure to induce some degree of psoriasis. The same affection is seen also on the soles of the feet, but in a less severe form, and rarely accompanied with fissures, as the feet are much better protected from cold, and very seldom exposed to the air while moist.

Diffuse psoriasis is sometimes seen on the scalp, producing an inflamed state of the skin, and a copious formation of white scales: in some instances the bulbs of the hairs become affected, and baldness is the consequence. The skin around the different natural apertures of the body is also subject to psoriasis, which, from the movements of the parts, is almost always productive of painful fissures. Thus it is met with on the edges of the eye-lids (*psoriasis ophthalmica*), the lips (*psoriasis labialis*), the nostrils, and on the verge of the anus and prepuce (*psoriasis preputialis*). When the lip is affected with psoriasis, it is most commonly the prolabium of the under lip: its causes are obscure, but Rayer (Maladies de la Peau, t. ii. p. i. p. 35,) states that he has twice observed it in persons who were great talkers, and addicted to the practice of biting their lips. The scrotum is likewise subject to this disease, and that generally in the inveterate form (*psoriasis scrotalis*).

Treatment.—The treatment of psoriasis is rendered of much greater importance than that of many other cutaneous diseases by the severe suffering which in many of its forms it produces; by its long continuance, sometimes for a lifetime; and by the obstinacy with which, after an apparent cure, it returns on a change of season, or the application of some slight occasional cause. It very seldom exists to any considerable extent along with a general healthy state of the frame: the system is usually either oppressed by the effects of a luxurious and indolent mode of life, or enfeebled by bad health, or by scanty nourishment and clothing, neglect of cleanliness, and the other concomitants of poverty. In both of these cases a change in the mode of living and in the state of health must be accomplished before we can hope to derive permanent benefit from the employment of remedies. A strict regimen, extending to every particular of diet, clothing, and exercise, suited to the peculiarities of the individual, must be the first step in our treatment. Should much irritation exist, and the strength of the patient permit, blood should be taken by venesection or cupping; and in the local varieties, such as the palmar and ophthalmic, leeches in the vicinity will be found useful. A general antiphlogistic regimen should be pursued, the use of spirituous liquors abandoned, and even wine and ale very sparingly, if at all, allowed; pickles, sour

fruits, vinegar, shell-fish, baked meats, pastry, highly seasoned dishes, and other indigestible food, should be carefully avoided. The bowels ought in every instance to be freely opened and kept in regular order: in many cases a sustained purgative treatment by calomel and saline medicines has succeeded in effecting a cure. In the hands of M. Biett (*Schedel et Cazenave*, Abrégé pratique des Malad. de la Peau,) this mode of treating psoriasis has proved highly advantageous; but it has been strongly opposed by Willan and Bateman, whose opinion on this subject has tended in no small degree to prevent British practitioners from making a fair trial of its efficacy. Of this practice our own experience does not enable us to speak with confidence; but we believe that it will be found to be suited only to those cases where there exists a tendency to plethora. Psoriasis, we have already stated, is sometimes combined with an opposite condition of the system, as it is met with in delicate chlorotic females. In these a course of tonic medicines, consisting of the preparations of cinchona and steel, will be necessary, if not as the immediate means of cure, at least for the purpose of preparing the body for the successful employment of other remedies.

Mercurials as well as purgatives have been denounced in general terms by Willan and Bateman, (*Willan*, vol. i. pp. 183, 184; *Bateman*, Synopsis, p. 43,) as unsuited to the treatment of psoriasis; and it must be admitted that the full action of mercury in this disease is positively injurious, as Willis (De Medicin. operat. Opera, p. 292,) long ago discovered. But it will not be denied that this remedy, when judiciously managed, in small and alterative doses, possesses a great power of correcting many of the disordered states of the digestive organs, and of restoring to the skin a soft and perspiring condition. The mercurial pill, mercury with chalk, Plummer's pill, and corrosive sublimate, have in our hands proved very serviceable, both in psoriasis and other scaly affections. One of the numerous remedies which have been employed internally for the cure of this disease is sulphur: it may be considered to act both as a revulsive, and by its immediate effect on the skin, through the pores of which, even under scaly disease, it is exhaled in the form of hydro-sulphurous gas. Among the different modes of exhibiting this popular remedy, may be enumerated the sulphureous mineral waters, sulphur conjoined with soda, with magnesia, or with cream of tartar; and, lastly, the diluted sulphuric acid, which was given by Dr. C. Smyth in very large doses, and, according to his report, with excellent effects. (*Smyth*, in Medical Communicat. vol. i. p. 191.) It is proper here to remark, that the sulphuric acid, when taken diluted, undergoes decomposition in the alimentary cavities; and that by its continued use the body becomes impregnated with sulphur, just as when that substance itself has been administered.

We are furnished with still more powerful remedies of a revulsive character in the tincture of cantharides and the different preparations of arsenic. The former of these was first recommended by Dr. Mead* in cutaneous diseases; and since his time its reputation has undergone many vicissitudes. Dr. C. Smyth, Dr. Falconer, and Dr. Willan, speak of the tincture of cantharides as altogether inefficient in the treatment of scaly disease; but M. Biett, (*Schedel et Cazenave*, Abrégé pratique,) at the Hospital St. Louis, has revived the use of this medicine in psoriasis, and found it to possess great efficacy. Our own experience has convinced us of its utility, but we have been repeatedly obliged to relinquish its employment in consequence of its effects on the urinary and generative organs. Arsenic, which was first introduced by Dr. Fowler in the treatment of squamous affections, has maintained its character among British practitioners with little or no interruption, and has even gained a place in the estimation of the physicians of France, notwithstanding the denunciations of the school of Broussais. M. Biett uses the solutions of Fowler and Pearson, and has also introduced into practice the arseniate of ammonia, of which he speaks very favourably. He employs, likewise, with advantage, the arsenical pill formed of the protoxide and black pepper: each pill contains one-thirteenth of a grain of arsenic, and two daily are considered by him as the maximum dose. Iodine is another medicine of the revulsive class, from which we anticipate very beneficial results in the treatment of psoriasis, but as yet our limited trials do not enable us to speak of its effects with confidence. Before taking leave of these powerfully acrid substances, it is necessary to caution the younger portion of our readers against employing them during the existence of constitutional disturbance or irritation of the digestive organs, and to point out the necessity of attentively watching their effects, that any inflammatory movement or deleterious influence on the stomach or brain may be immediately counteracted. In some cases, when the appearance of such symptoms has obliged us to suspend these medicines, great benefit has been obtained from bloodletting, both in allaying the irritation which they had caused, and subduing the cutaneous affection.

There remain to be noticed some other remedies of the revulsive tribe which possess a certain degree of efficacy in scaly diseases. The tincture of white hellebore (veratrum album), and pitch given in large doses in pill, are both highly recommended by Dr. Bateman: from the latter we have seen beneficial results. The liquor potassæ has occasionally proved useful in psoriasis, as we have repeatedly experienced; and when this disease exists along with the lithic diathesis, as in gout and calculus, (no unusual combination,) its property of correcting acidity affords a prospect of decided benefit. (See the case of Horace Walpole, Phil. Trans. vol. 50, p. 206.) The bitter sweet (solanum dulcamara) has likewise obtained considerable reputation for the cure of psoriasis; its effects are rather narcotic than revulsive; but its sensible action, in the doses usually prescribed, is seldom very obvious. The belief in its efficacy as a remedy for scaly eruptions rests on unexcep

* Medicina Sacra, cap. ii. Although Dr. Mead's remarks refer professedly to the leprosy of the Jews, he appears to have had in view scaly diseases; for he describes, as an instance of leprosy, the case of a countryman, whose skin was glistening like snow with white scales, which, when rubbed off, left a raw surface exposed. This individual seems to have laboured under psoriasis inveterata.

tionable authority; (*Crichton*, in Willan on Cutaneous Diseases, p. 145); and the remarks of Dr. Gardner (in Med. and Phys. Journ. May, 1830) on the defective mode in which the decoction is usually prepared may serve to explain much of that disappointment which has of late been experienced in its exhibition.

Psoriasis being remarkable for the severity of its local effects, we are naturally led to attempt its cure by means of topical remedies; and although these alone will rarely prove effectual, it must be acknowledged that, without their judiciously directed aid, we shall rarely if ever succeed in obtaining a satisfactory result. We are often enabled to relieve the patient's sufferings by such applications, as infusion of almond meal or of bran, decoction of poppy-heads, weak spirit lotion, emulsion of bitter almonds, lotions containing hydrocyanic acid, cream or fresh butter, neat's foot or almond oil, [or cod-liver oil]. A still more soothing effect on the whole frame will be produced by the use of a tepid or moderately warm bath, to which a quantity of bran or a little carbonate of soda or potass has been added. A favourite remedy among the French for the same purpose is a bath of greasy dish-water (eau de vaisselle grasse)—rather an unseemly application. After due attention has been paid to the state of the general health, and when the severity of the local irritation has somewhat subsided, we may proceed to employ the warm bath, from 96° to 104°, with such friction as can be easily borne, in order to stimulate and soften the skin, and detach the scales. The simple vapour-bath, or this combined with sulphur or iodine, affords still more powerful means of softening the surface and exciting the skin to a healthy performance of its functions, and the secretion of a sounder cuticle. Such baths certainly form a valuable addition to our means of curing every variety of scaly disease, and often enable us to subdue affections which would formerly have resisted all our remedies. (*Rapou*, Traité de la Méthode fumigatoire.) But the vapour-bath, in its different modifications, is a remedy which always demands the watchful care of the physician: its excitement not unfrequently proves too great, requiring its suspension, or even the abstraction of blood. Baths of mineral waters, especially those impregnated with sulphur, have long been resorted to with benefit for the cure of psoriasis; and similar baths, formed artificially by means of the sulphurets, will often be found of great service, provided the disease is not in too active and irritated a state. In the slighter forms of psoriasis, as when it is confined to the face and forehead, a sulphurated lotion, prepared by infusing sulphur in boiling water, has often proved highly advantageous. The internal use of the sulphureous mineral waters, or of corresponding medicines, may be beneficially conjoined. Saline mineral waters and sea-water have likewise been employed in this disease, and from the latter we have seen excellent effects; but chiefly we believe from the influence of sea-bathing in improving the general health. In one very aggravated case of diffuse psoriasis, where the disease was in an active and increasing state under the use of the arsenical liquor, the patient commenced sea-bathing, and anointed the eruption merely with fresh butter: a speedy amendment followed, and the affection almost wholly disappeared in about a month, but it was not eradicated.

Although the transpiration from the affected surface is much obstructed in psoriasis, it is not wholly suppressed; and there are still left many interstices from which an insensible perspiration is exhaled. By covering the part with oiled silk, we retain this and preserve the skin in a continual vapour-bath, which softens it, and tends to restore it to a healthy state. The benefits of such a practice have been long known in the treatment of several local forms of psoriasis, as that of the palms; and the plan may be usefully extended even to cases where a large part of the body is affected. Great benefit is also derived from merely protecting the patches of psoriasis from the action of the atmosphere, which is remarkably evinced in that of the lips, nostrils, and eyelids. Any mild adhesive cerate will answer the purpose; but it is usual to employ one containing a very small proportion of the nitrate, or the white precipitate of mercury. Dr. Willan states that in psoriasis of the lips, nothing but the mildest cerate or plaster can be borne; and that its constant use is indispensable to a cure.

But ointments are employed in psoriasis, not merely to protect and soften the surface, but as strong topical stimulants, to excite the healthy actions and remove the thickening of the skin. Those in most common use are, the ointment of nitrate of mercury, the pitch ointment, and one composed of equal parts of these two. We are indebted to M. Biett for the introduction of remedies of vastly greater power, formed from the preparations of iodine. Of these the most efficient are the ointments of the iodides of mercury and sulphur,* which we have found fully to merit the praises he has bestowed on them. It is necessary for the success of these stimulating ointments that they should be well rubbed into the spots and patches at bed-time, washed off with soap and water in the morning, and if the situation of the eruption permit, again rubbed in, and the same process gone through twice daily. In cases of solid thickening, both of the cuticle and cutis, sometimes seen, particularly in the knee and elbow, where even these powerfully stimulating ointments prove unavailing, we have derived great benefit from the application of strong acetic acid. The agency of this liquid in removing the most obstinate horny warts, and thinning the cuticle, when vinegar and sponging have been long employed, first directed our attention to it as a remedy in psoriasis; and the result of our trials has been highly satisfactory—the diseased cuticle separating in flakes, and a new surface being exposed of a much more healthy character. The application of the acid, which requires to be repeated, is hot and painful, especially when there are excoriations or fissures, but these ought to be protected by some mild cerate. Blisters have likewise been had recourse to in obstinate states of psoriasis, and with marked benefit; but their effects appear to

* *Recipe.*—P. tenuiss. proto iodid. hydrarg. gr. xii.—sc. ii. Axung. purific. oz. i. *m.* ut fiat ung.

Recipe.—P. tenuiss. deuto iodid. hydr. gr. xii.—sc. iss. Axung. purif. oz. i. *m.* ut fiat ung.

Recipe.—P. tenuiss. iodid. sulphuris, sc. i.—sc. iss. Axung. purif. oz. i. *m.* ut fiat ung.

be less permanent than those of the acetic acid. When there is oozing of fluid from the patches of psoriasis, advantage will be derived from the use of astringent lotions, as the liquor alum. compos. and solutions of corrosive sublimate, or of sulphate of copper; and when the effusion of moisture has thus been dried up, and the parts are a little hardened, which readily takes place, some mild adhesive cerate may be applied at bed-time and washed off in the morning. By steadily persevering in this plan, very troublesome cases of the local forms of psoriasis have been completely cured. In some of these obstinate varieties, particularly that of the scrotum, fumigations with sulphur and with cinnabar have effected a cure.

[Recently, anthrakokali and fuligokali, simple and sulphuretted, have been recommended both internally and externally. (See the writer's *New Remedies*, 4th edit. p. 57 and p. 321, and Mr. E. Wilson, *A Practical and Theoretical Treatise on Diseases of the Skin*, Amer. edit. p. 351, Philad. 1843.) Cantharides have likewise been employed externally. Dr. Davidson (*Lond. & Edinb. Monthly Journ. of Med. Science*, Dec. 1841) noted the comparative effect of iodide of sulphur, and the acetum cantharidis of the Edinburgh Pharmacopœia in an inveterate case of several years' standing, in which a variety of remedies had been tried in vain, and found the latter more efficacious. (See Lepra.)]

The long list of remedies which has now been reviewed, furnishes in itself abundant evidence of the intractable and rebellious nature of psoriasis; but it is not without reason that they have been enumerated, for it is well known to those familiar with chronic diseases of the skin, that a change of remedies is frequently required; and that one will at length succeed when all others have failed.

Should our efforts to effect the cure of psoriasis have proved unavailing, it will be proper, if the patient's circumstances and general health permit, to recommend his removal to a more genial or even a warm climate, when the habitually increased activity of the cutaneous functions, and the change which his constitution is likely to undergo, may render successful the modes of treatment which were previously without effect.

When the cure of psoriasis is about to be accomplished, the scales rapidly drop, and soon cease to be reproduced; the thickening and inflammation of the skin gradually yield; at length the affected parts appear as if slightly depressed, having a somewhat darker tint than the healthy skin, and occasionally we observe around these cicatrices a pale or white border. The completion of these changes on the diseased surface affords satisfactory evidence of the cure of psoriasis; and without this cicatrization, the mere absence of scales amounts only to a temporary amendment.

W. Cumin.

[PTYALISM, or SALIVATION.—An increased secretion of saliva may arise from various causes and is frequently altogether symptomatic,—as in children, during dentition. When it occurs as a symptom, it will be described under the primary affection.

Ptyalism may be considered under two heads—the *first* embracing that which arises spontaneously, often without any obvious cause, and the *second* that which is produced by mercury.

1. Spontaneous Ptyalism.—Salivation occasionally occurs, especially in children, with all the characters of mercurial salivation, when not a particle of mercury has been administered. It is essential to bear this fact in mind, inasmuch as blame is frequently attached to the medical practitioner, where such symptoms arise, under the idea that he has been administering mercurials to an objectionable extent. Salivation may be induced by various articles,—as by iodine, the preparations of gold, copper, antimony, arsenic; and it is said, by Dr. Watson, (*Lectures on the Principles and Practice of Physic*, Amer. edit. p. 434. Philad. 1844,) that it has followed the employment of castor oil, digitalis, and opium. Cases are on record, in which it has occurred to a profuse extent, without any obvious cause. Thus, one is related in which two or three pints of saliva were discharged daily, for some time. The affection ceased under the use of gentle cathartics. Many similar examples are on record.

Treatment.—Should such a case present itself, it will be important to examine, whether there be inflammation, or irritation, from carious teeth or otherwise, in the mouth. Should no adequate cause be discoverable, the disease must be referred to some constitutional or local affection of the glands, which gives rise to secretory irritation, and consequent hypercrinia.

Certain of the remedies, recommended under the next form of ptyalism, may be found serviceable.

2. Mercurial Ptyalism. — **Diagnosis.** — The symptoms of mercurial salivation are well known; but fortunately, not so much so as formerly, in consequence of the comparative unfrequency of the affection, owing to our improved knowledge of the therapeutical effects, and *modus operandi* of mercury. Prior to the supervention of full ptyalism, phenomena present themselves, which indicate that the mouth is *touched* by the mercury. A disagreeable coppery taste is experienced, accompanied by a painful feeling or soreness in the mucous membrane of the mouth, and in the teeth, which appear to be loosened in their sockets; to these phenomena succeed swelling of the gums, inner surface of the cheeks, tongue, and soft palate, which become hot and painful, and, where the cheek and tongue are pressed upon by the teeth, they are found indented. The gums now fall away from the teeth, and at the edges a whitish secretion is poured out, which has an albuminous appearance. This secretion seems, indeed, to invest the mucous membrane of the mouth, which consequently does not appear to be as red as the symptoms would indicate. The parts that are the most swollen and subjected to pressure soon begin to ulcerate, and the ulcers spread, and present a greyish, flabby and fungous appearance, blood readily flowing from them. The lymphatic ganglions, situate between the parts affected, and the centre of the lymphatic system, now become swollen and painful; and, at times, the patient is unable to separate his jaws, and almost to swallow, owing to the excessive tumefaction of the parts. From the very commencement, the breath has a peculiar fetor, and this augments, so that at the height of the disease it is strong and disagreeable. As soon

as the mouth is touched by the remedy, the flow of saliva, and of the mucous secretions of the mouth becomes so much augmented, that the individual is compelled to eject the fluid continually, and where complcte ptyalism has set in, the quantity evacuated is occasionally enormous. Eight pounds in the 24 hours have been mcntioned by M. Andral, (*Cours de Pathologie Interne,*) but this is not the limit. Sixteen pounds are said by Most, (Art. Ptyalismus, *in Encyklopäd. der gesammten Med. und Chirur. Praxis,* Leipz. 1837,) to have been discharged in this way ; the average quantity in health not exceeding four ounces, according to Mitscherlich, (*Rust's Magazin,* xxxvi, 491; see also, Rullier et Raige-Delorme, Art. Digestion, in *Dict. de Méd.* 2de édit. x. 300, Paris 1835.) This increased flow may exist — to a greater or less extent—for many days or even weeks.

At one time, the effect of the remedy in syphilis was measured by the quantity of saliva discharged: —if the disease were of a certain duration, the patient must spit a quart; if of a longer, two quarts, and so on: but now, since the conviction of the practitioner is, that salivation is rarely or never necessary, and that it is rather to be dcplored,— inasmuch as the increased discharge exhausts and irritates, without being of itself beneficial, — the practice has been abandoned, and if we meet with excessive ptyalism, it is generally in those who are easily affected by mercury and in whom the affection supervenes rapidly ; or in those in whom the remedy has, by accident, been persisted in for a longer period than was contemplated. The books were formerly filled with descriptions of the horrible accidents induced by mercurial ptyalism, some of which the author has witnessed ;— as extensive sloughing, loss of teeth, caries of jaw bones; protrusion of the tongue from the mouth; adhesions of the tongue and cheeks, &c. &c.; with, at times, excessive febrile irritation, marasmus, and death. This last event was, however, uncommon. Usually, after a tedious convalescence, the sufferer was restored to health, but occasionally the system received an injury from which it never wholly recovered.

Although thc plan of exciting profuse salivation for the cure of syphilis may now be considered as generally and properly exploded, and, therefore, these cases of ptyalism are comparatively rare, we still now and then observe thc deplorable effects of mercury pushed with equal incaution for the treatment of many of our bilious and other fevers. Not many years ago, an interesting casc fell under the author's care, in which the lower jaw became firmly closcd in conscquence of the formation of ligamentous bands, and of the contraction that had occurred during the cicatrization of mercurial ulcers of the mouth; the bones of the jaw were carious, and portions of them exfoliated; yet, by careful management, —improving thc general habit, and separating the jaws gradually by an instrument contrived for that purpose, they became movable. Within the last few years, the writer has known of other similar cascs, the subjects of which had sought Philadelphia for surgical relief under their deformities.

Causes.—The term mercurial ptyalism sufficiently indicates the exciting cause; but a few remarks are necessary on predisposition. Unquestionably, age has its influence. It is almost impossible,—wholly so, perhaps, in most cases,— to salivate a child under two years of age. There is something in the peculiar evolution of organs at this age that prevents it ; yet, after the age of two, children become very susceptible of mercurial influence, and remain so, although not perhaps to an cqual degree, throughout the remainder of existence. There is, likewise, a marked difference in individuals as to their susceptibility to the action of mercury, — some being affected by the smallest quantity, whilst it is impossible to salivate others by any amount. Temperature has some effect, and exposure to cool air. In hot weather, especially if the individual take exercise, the mercury appears to pass off by the cutaneous transpiration; and, on the other hand, the repression of the transpiration frequently induces ptyalism. Constipation also appears to favour the action of mercury, as diarrhœa usually prevents or retards it.

It is difficult to account for the action of mercury in inducing ptyalism. It obviously enters the blood, for it has been detected in that fluid; and, in this way, probably, it excites a new action not only in the salivary glands, but apparently, in almost all the secretory organs of the economy. M. Andral (*Hématologie Pathologique,* Paris, 1843,) examined the condition of the blood in some cases of mercurial stomatitis, but did not discover any difference between it and the blood of other inflammatory affections. He never witnessed a diminution of fibrin, as is supposed to follow its use by those who prescribe it in certain diseased conditions to diminish the plasticity of the blood, as in diphtheritis, and, indeed, in inflammatory affections in general.

Treatment.—If the febrile and inflammatory symptoms run high, blood-letting—general and local — may be demanded ; but this can seldom be the case. It is a favourite remedy, at the commencement, with one distinguishcd individual, M. Cullerier. Generally, it is best to administer saline cathartics, which act in a twofold manner, both as depletives and revellents.

They should be given to the extent of producing at least two or three liquid evacuations in the twenty-four hours, for the first two or three days, unless their use is contra-indicated. The preparations of sulphur — sublimed sulphur, and sulphuret of potassium — combined, or not, with sulphurous baths, have been long prescribed; under the idea, that the sulphur would exert some chemical agency in modifying the action of the mercury. Few entertain this opinion at the present day: sublimcd sulphur is, however, a gentle and pleasant laxative, and may be given with that vicw.

In the early period of the disease, emollient and warm collutories are found to be the most soothing. These may consist of mucilage of gum arabic, flaxseed tea, infusion of the slippery elm, and similar mucilaginous articles; but, in the after stagcs, greater advantage is derived from agents of a more excitant character. Various astringents have been used for this purpose, such as the acetate of lead, the sulphate of zinc. and

the sulphate of alumina and potassa. The author thinks that he has derived as much benefit from the solution of chlorinated lime, and from that of creasote, as from any other agents. It must be borne in mind, however, that the art of medicine, in the generality of cases, does not appear to possess much power over the disease, and that whatever internal or external remedy is employed, *time* is an essential element in the cure. A collutory of chlorinated lime not only appears to diminish, in many cases, the excessive secretion from the salivary glands, but speedily mitigates the sense of burning in the mouth, induces the healing of the erosions of the mucous membrane, and corrects the mercurial fetor. If either this, or the creasote wash, should be too stimulating, it must be reduced by the addition of water.

By many, the internal use of iodine has been highly extolled; yet, in the experience of others, its efficacy has been doubtful. It may be given in the form of the tincture, (ten drops, three times a day, in gruel.)

If ulcerations exist, and they resist the local management above directed, they may be treated upon the plan advised under the head of Stomatitis. M. Ricord prefers applying strong muriatic acid to the ulcerations, repeating the application every day, or every other day,—the bleeding of the surface presenting no obstacle. The acute pain it produces soon ceases, and nothing, he thinks, equals its beneficial effects. Should the pain be so severe as to preclude rest, opium or its preparations may be freely administered.

Recently, a case of mercurial ptyalism, occurring in a child four years of age, which had continued for two months and a half, and had resisted all the usual remedies, yielded to warm baths acidulated with equal parts of nitric and muriatic acid, prescribed by Dr. Baumgartner.

The diet, throughout the severity of the disease, should consist of farinaceous substances; but, later on, milk, broths, and the lighter preparations of animal food, may not only be permitted, but be advisable.

ROBLEY DUNGLISON.]

PUERPERAL DISEASES.—The object of this article is to present a general view of the parturient and puerperal states, and of the various diseases which may occur, singly or combined, in their varied circumstances. Such views of an important class of morbid affections are frequently of more practical value than the most laboured treatises on individual diseases. But the present class is one of peculiar moment: no other is so complicated in itself, and none excites such deep interest in the minds both of friends and of the physician.

The class of puerperal diseases must be viewed as embracing all those morbid affections which arise out of the state of pregnancy,—the act of parturition, the complicated condition of the system and organs which immediately follows parturition, and the function of lactation.

In the early period of pregnancy, several organs, but especially the stomach, sympathize with the new condition of the uterus, and suffer severely.

In the later periods of pregnancy several causes combine their influence especially to endanger the state of the brain. It is upon the conjoined and separate operation of these causes that our attention should be particularly fixed, in regard to the diseases of this period; for it is frequently by their co-operation alone that their morbid influence upon the brain is brought into activity, whilst it may occur, afterwards, that one or even several of these causes may be removed, and yet a remaining one may renew or continue the morbid effect upon the brain, which they had conjointly begun. The causes which co-operate in the last period of utero-gestation, in inducing a morbid state of the brain, are chiefly uterine and intestinal irritation, concurring with the actual pressure of the gravid uterus upon the various viscera and vessels situated behind it, and the state of plethora of the vascular system especially, occasioned by this pressure.

During parturition, the contractile efforts of the uterus and of the abdominal muscles add another source of danger to those already mentioned; and it is at this period that the brain is most subjected to fulness and pressure, and that convulsions or even apoplexy are apt to occur.

Several sources of danger are removed when delivery has taken place; and yet this is not always sufficient to protect the patient from an attack of convulsion, for this terrible affection has first occurred even after delivery had been effected. In this case, especially, we suspect that a state of intestinal load and irritation has been the exciting cause of the convulsion. This observation confirms the remark already made, that when several causes have co-operated to induce a state of danger, some may be removed, and yet, if one remain, it may lead to the most disastrous events. This peculiarity in the study of puerperal diseases cannot be pointed out too often or too strongly.

Convulsions do occasionally occur after delivery, even although the system be in a state of exhaustion from hemorrhage. The state of general exhaustion is not, we believe, incompatible with a state of fulness of the brain; but this kind of convulsions will be found, we think, frequently to involve also a state of intestinal load and irritation.

The danger may arise, however, immediately after delivery, more directly and simply, from a state of inanition and exhaustion, the effects of an emptied condition of the uterus and abdomen, of abstracted pressure upon the viscera and vessels along the spine, and perhaps of loss of blood.

To these sources of danger after delivery must also be added the effects, perhaps, of protracted suffering, of violent pain, of mental alarm, and of what may be termed the "shock" of parturition.

There is another series of puerperal affections which do not occur for the most part until some hours at least after delivery. These affections consist principally of uterine, peritoneal, or venous inflammation, of the effects of intestinal irritation, of the effects of loss of blood, or of two or more of these combined. There are two other sources of irritation in the condition of the mammæ, and occasionally of the uterus; and there is that terrible disease, the epidemic puerperal fever.

Considering the important and sudden change which takes place in the condition of the uterus in parturition, we cannot be surprised that this organ should frequently be the subject of inflammation in the puerperal state. Neither can it be

matter of surprise that its appendages, the adjacent viscera, and the peritoneum at large, should not unfrequently participate in this morbid condition. And when we further consider the degree of violence to which the brain has been subjected during parturition, we must be led to expect that this important organ should be left by that process in a state of proneness to inflammation; and this is precisely the case: for next to the viscera of the abdominal cavity, the brain is perhaps the organ which is most apt to become affected by puerperal inflammation, though in fact puerperal phrenitis is a far more rare disease than has been supposed.

We have further to consider the peculiar condition of the internal surface of the uterus after parturition. M. Cruveilhier has compared it to that of a wound. However this may be, phrenitis and inflammation of the absorbents are among the most formidable of puerperal diseases, diseases arising from this peculiar state of the internal surface of the uterus.

There is another not less fertile source of puerperal disease in the state of the alimentary canal after delivery. This state consists, in general, of a loaded or disordered condition of the large intestines, but is sometimes also induced by improper things taken into the stomach. It is most important to observe that the effects of stomachal or intestinal irritation are very similar to those of inflammation, as it affects the head or abdomen; for on the just diagnosis of these cases depends the proper application of the remedies.

Similar observations apply to the effects of loss of blood when these are of the remote character, and attended by the phenomena of reaction.

In this case the head is apt to be so affected as to lead to the idea of inflammation of the brain; and the heart, so as to present the symptoms of disease of this vital organ.

But it is rare that these sources of disease act thus distinctly; it is far more usual to observe them co-operating to produce mixed cases. One of the most frequent of these is puerperal mania. It is in such complicated cases that all the attention and energies of the mind are required to appreciate the influence of each, and to adapt the remedies to this complicated form of disease.

There is not unfrequently, also, a source of irritation in the state of the uterus itself. A certain degree of after-pain is usual in almost every case; but a state of irritation and pain is frequently kept up by the presence of clots of blood, and the efforts for their expulsion. This state of the uterus is full of dangers; not in itself, but by masking and concealing the beginning of dangerous diseases: pain of an inflammatory kind is too apt to be neglected, under the impression that it is but the usual after-pain.

A similar remark may be made in regard to the irritation excited during the establishment of the secretion of milk. This process is apt to be attended by pain, fever, and affection of the head, which frequently mask the beginnings of puerperal disease.

Both these sources of irritation concur to add complexity to the character, and difficulty to the diagnosis of puerperal diseases, and to constitute that peculiarity of this study to which we have already alluded

The first of these classes of disease might perhaps be denominated *parturient*, whilst the second might be distinguished by the epithet *puerperal*; the former occurring chiefly in or near the act of parturition; the latter usually some hours afterwards. There is a third class of morbid affections which follow still more remotely upon child-bearing, and which consist principally of the more continued effects of intestinal disorder or of loss of blood, and issue, for the most part, in an inability to support the drain occasioned by lactation.

A fourth series of puerperal maladies, using this term in its most extended sense, arises out of undue lactation itself. They consist in the various forms and effects of exhaustion, and constitute a most important and interesting subject for renewed inquiry; for we believe them not to be at present by any means fully understood.

There is still another consideration which is full of interest in regard to puerperal diseases,—namely, the state of health of the patient previous to her confinement. That which most frequently modifies the puerperal state is disorder of the general health, which may possess very various characters. It frequently occurs, from such a state of general disorder, that the recovery after confinement is tardy, the secretion of milk scanty, or even morbid, affecting the health of the infant; and that there are many local affections, especially of the head or of the heart, which are full of pain and suffering.

We have now taken a rapid survey of the principal causes of puerperal diseases. It may be truly said that many of these causes co-operate in every case; but it is also true that each puerperal disease is to be referred to one or two of these causes more especially. Every case of puerperal affection may, therefore, be considered as a case of modified disease, requiring that the mind of the physician be active and comprehensive, so as to embrace the numerous circumstances of the disease. This is true in a degree which scarcely obtains in any other class of diseases; and it is on this account that we have represented the study of puerperal diseases as requiring peculiar habits of inquiry and investigation.

Of the morbid affections which occur in the parturient state.—The term parturient is adopted to express the condition of a person just before, just after, and during the act of parturition A brief notice of the morbid tendencies of this state is a necessary introduction to the more detailed account of some of the morbid affections which occur in that which may perhaps be more properly termed puerperal. The distinction between the parturient and the puerperal states will be found to be at least of great practical utility.

We have already cursorily alluded to the principal causes of apoplexy and convulsions, as they occur in the last stage of utero-gestation, and in the act of parturition. It is our present object to enter into this important question with somewhat more detail.

The first cause enumerated as conducing to these affections of the brain was uterine irritation. That this species of irritation does indeed dispose to disease of the brain, is sufficiently obvious from the occasional occurrence of convulsions in cases even of dysmenorrhœa or painful menstruation.

A second exciting cause of affection of the

brain, probably not very different in its nature from the former, is found in the parturient efforts of the uterus when labour has begun. The effects of labour-pain upon the vascular system of the head is sufficiently seen in the flushed state of the countenance; and the attack, or the recurrence of convulsion, not unfrequently takes place with each uterine effort.

With the uterine efforts must, however, be conjoined those of the abdominal and other muscles, in our estimation of the influence of labour-pains upon the state of the brain.

The third cause of affection of the head in the parturient state is stomachal or intestinal load or irritation. It appears almost unnecessary to adduce any example of the influence of these causes upon the vascular system and nervous origins within the head. The presence of indigestible substances in the stomach, and of indurated or otherwise morbid fæcal matters in the large intestines, are amongst the most usual causes of apoplexy and convulsions in those who are predisposed to these affections, and especially in the puerperal state. The late Dr. John Clarke published an interesting and important paper, to which we shall have occasion to revert hereafter, upon the morbid influence of oysters, taken at this period, upon the brain; and it cannot be doubted that other indigestible substances have frequently, perhaps unsuspectedly, produced the same deleterious effects. One of these effects was convulsion. And it is to be particularly remarked that the cases published by Dr. Clarke all occurred after delivery, and of course even after some of the predisposing causes of puerperal convulsion had ceased to operate.

But a still more frequent concurrent cause of convulsion or of apoplexy in the parturient state is a loaded condition of the large intestines. The operation of this cause is frequently made obvious by the effects of purgative medicines and enemata in these cases, both in the relief they effect in the symptoms of affection of the brain, and in the character of the alvine evacuations: the quantity of scybalous fæces which have thus been evacuated in some instances would appear incredible, were not the torpid and dilated condition of the intestine taken into the account.

Nor can there be any doubt that the gravid uterus itself acts by its size and by its pressure upon the descending aorta, in inducing fulness of the vessels of the brain in the last period of utero-gestation. It is on this principle that delivery frequently secures the patient against the recurrence of the fit of convulsion. When the pressure of the gravid uterus falls more particularly upon the vena cava, the effect of interrupted circulation is of course observed in the lower extremities, chiefly under the form of œdema, but perhaps of phlegmasia dolens.

It usually happens, as we have observed already, that apoplexy or convulsion occurs in the parturient state from the conjoined operation of several of these causes; and it is only by an attentive consideration of all of these sources of danger, that the attack is to be prevented in the first place, and its recurrence in the second.

It is important also, with the view of prevention, to consider the probable condition of the encephalon itself immediately leading to an attack of convulsion or apoplexy. It is doubtless one either of irritation or of fulness. Every cause of these morbid states of the brain must therefore be carefully removed and avoided, whilst their effects are combated by the most vigorous remedial measures.

This is the more important, because each recurrence of convulsion is not only attended by immediate danger, but aggravates the morbid condition of the brain and augments the tendency to the repetition of the paroxysms of convulsion. The same observation may be made of each contractile effort of the uterus and abdominal muscles during parturition, which, like the fits of hooping-cough in other circumstances, has in some instances led to convulsion.

The state of the system which obtains immediately after delivery is in many important circumstances different from that which exists during pregnancy and in the act of parturition. The emptied state of the uterus and abdomen constitutes in itself a source of inanition; and there is usually more or less of loss of blood, and sometimes even an extreme degree of hemorrhage, so that the system in general must be considered to be in a state of exhaustion. There can be no doubt that this very exhaustion alone has in some instances induced convulsion; but it is probable that in many, some of the causes of this terrible affection which have been mentioned, and especially a state of uterine, stomachal, or intestinal irritation, have concurred to produce this effect.

The more usual immediate consequences of delivery and of uterine hemorrhage is a state of syncope; this is more or less severe and alarming according to the degree of loss of blood and of the susceptibility to its effects, and varies from the slightest degree of faintishness to such a state of syncope as may endanger life.

Similar effects are sometimes to be attributed to the protracted sufferings of a lingering labour, in other cases to the violence of pain, and in others to alarm and dreary apprehensions and anticipations on the part of the patient. These circumstances sometimes lead to sudden death, an event which may occur immediately upon delivery. In such cases, cordials given during the last stage of labour, the recumbent position guardedly preserved, and the immediate and careful application of the abdominal bandage, may save the patient.

Perhaps the condition of the system under the influence of some of the circumstances of parturition cannot be better expressed than by the term 'shock;' and it may be aptly compared to a similar state under very different circumstances, and especially those of a painful operation. This state of shock seems to consist of a partially suspended power and action in the system. It may be suddenly fatal, or it may yield to reaction, which may or may not pass the boundary of health; or, lastly, after some feeble efforts, it may lead to a gradual but irretrievable sinking of the vital powers. This subject has not been sufficiently noticed in medical writings, especially in connection with the parturient state.

One of the influences of shock still requires to be mentioned. Many causes of disorder may long remain dormant, or may be affecting the system

in the most gradual manner only, until they are called into a more active operation by some kind of shock. This is particularly true in regard to intestinal irritation. This cause of disorder may long subsist in an inactive state, until, by the occurrence of some shock to the system, it is brought into but too effective operation. It is for this reason that the effects of intestinal irritation are so frequently observed in the puerperal state and after various accidents, without which this cause of constitutional derangement might have long remained inoperative, or at least insufficient for the production of acute disease.

In the treatment of apoplexy or convulsions before delivery, and even after delivery, except in cases of profuse uterine hemorrhage, the principal remedy is bloodletting; the second object is the removal of all those exciting causes of the disease which have been mentioned; and the third is cupping of the occiput and neck.

In the case of hemorrhage, the remedies are still the removal of the exciting causes and cupping.

A state of exhaustion from loss of blood generally from the system, does not protect the brain from a state of vascular fulness. This is abundantly proved in the excellent paper of Dr. Kellie, in the Medico-Chirurgical Transactions of Edinburgh, and by the fact of the occurrence of convulsions, and even of apoplexy, in this state of exhaustion It is in this very case that cupping of the occiput is so strongly to be recommended. The brain, in some cases of exhaustion, is relieved by the topical abstraction of a very small quantity of blood; and this relief is not only obtained by a less expenditure of blood, but is more permanent than similar relief by general bloodletting.

[The signs of determination of blood, which often supervene on excessive hemorrhage, are, however, often owing to the irregularity of vascular action induced through inordinately and irregularly excited nervous erethism in the stage of reaction—and, as the writer has said elsewhere, (*General Therapeutics and Materia Medica*, ii. 150, Philad. 1843,) they are best treated by a full dose of opium, sufficient to allay the nervous excitement, after which the vascular tumult speedily subsides.]

The next point in the treatment is the removal, not of one or two, but of all sources of irritation—of all the possible exciting causes.

A point not less important than the treatment of these affections is their prevention. No means would conduce so much to this purpose as the invariable administration of copious warm-water injections at some period before or during labour. The large intestines would thus be relieved of their load, and a great and fertile source of future disease would be removed. And this remark applies not to affections of the head only, but to many other puerperal diseases.

Of the Morbid Affections which occur in the Puerperal State.—The morbid affections which occur in the puerperal as distinguished from the parturient state usually commences at such a period after delivery as may have given space for reaction to take place, after the state of inanition and exhaustion which usually obtains immediately upon parturition.

It should be observed, however, that there is scarcely a disease of the puerperal state which does not occasionally show itself before delivery. In these cases the disease usually remains stationary, or nearly so, until parturition has taken place, and then assumes its exasperated form.

In some instances, and those of the most serious kind, puerperal disease supervenes insidiously, and makes a slow and probably an unheeded and fatal progress.

Even of those puerperal diseases which commence by marked symptoms, the more serious are not always the most unequivocal in their mode of attack. Pure inflammation is, for example, less marked by rigor, heat, and other obvious symptoms, than are the effects of intestinal irritation. This is a point which requires to be enforced upon the attention of practitioners; for, in inflammation especially, it is of the utmost importance to detect the disease in its very origin.

The effects of intestinal irritation and of loss of blood are apt to produce symptoms of increased action resembling those of inflammatory disease, and prompting the use of evacuant remedies. This proceeding is attended by two sources of error: in the first place the symptoms are frequently relieved in the first instance,—a state of faintishness taking place of that of reaction,—and the physician is apt to judge that the remedy had relieved, but was used in too mild a degree to subdue the disease, and is thence led to a repetition of the measure: in the second place, after the first and second moderate use of the lancet, for instance, the reaction returns in a still more violent degree than before; and it is then imagined that the disease, though relieved, was not only not subdued, but had been suffered to make a fearful progress; the lancet is therefore again used, until it may be that the powers of the system yield, and sinking takes place of reaction; or, if the last bloodletting be considerable, the scene may be closed by a sudden and unexpected dissolution.

We now proceed to treat of each particular form of puerperal disease.

Of Puerperal Inflammation within the Abdomen.—Inflammation within the abdomen, as it occurs in the puerperal state, may be divided into three kinds; that which chiefly affects the uterus and its appendages; that which appears to be general over the peritoneum; and that which is confined to a portion of this membrane.

A distinction of still greater practical importance is that between the acute and the insidious forms of puerperal inflammation of the abdomen. Sometimes the attack is distinctly characterized from the beginning; at other times it is of the most insidious character, perhaps to be referred back to a date anterior to parturition, or even apparently issuing out of mere labour-pain. These are points which require to be deeply impressed upon the mind of the young physician, in order that they may induce in him that degree of watchfulness in regard to these diseases which they so imperatively demand.

Inflammation within the abdomen, of whatever kind it may be, is only to be ascertained by the presence of pain, induced or aggravated upon

pressure. This is the pathognomonic symptom of the disease. All the other symptoms are only accessory; and they are all, without exception, inconstant. In some insidious cases of abdominal inflammation, the tenderness even is only discovered by a careful examination; and there is sometimes pain under pressure when there is no inflammation.

These remarks will, we trust, lead to the most careful examination of the abdomen, and of the symptoms in general, in every case of puerperal disease.

The acute attack of puerperal inflammation within the abdomen is frequently marked by rigor. This is frequently in the worst cases only slight. We cannot sufficiently enforce this fact upon the attention of our readers. Some have imagined that there could be no puerperal inflammation of the abdomen without severe rigor; and they have generally supposed that severe rigor necessarily supposes an attack of inflammation. We can most unequivocally attest that both these opinions are erroneous, and contradicted by facts.

We would make precisely the same observations in regard to great heat of surface or fever. We have known many instances of acute puerperal inflammation within the abdomen unattended by heat of skin, and many cases resembling inflammation, but not in reality inflammatory, in which the heat of surface was extreme.

Frequency of the pulse is not a less uncertain indication of inflammation. We are enabled to say, from careful observation, that the pulse is but little accelerated in many cases of puerperal inflammation within the abdomen, whilst it is excessively and even alarmingly frequent in some cases in which inflammation does not exist.

In regard to pain and affection of the head, they are by no means essential attendants upon puerperal inflammation of the abdomen in its first stages, but, on the contrary, appear to denote another and different kind of morbid affection, which may exist alone or as a complication of inflammation.

Pure puerperal inflammation of the peritoneum is to be ascertained by an attentive examination of the abdomen. There is either pain increased upon pressure, or tenderness discovered upon pressure; and this is either general over the abdomen, or confined to the hypogastric region; or, lastly, in cases of partial peritonitis, to some other part of the abdomen. With the pain or tenderness there is frequently either general tumidity of the abdomen, or a local hardness; in the latter case it is frequently such as to denote an enlarged and inflamed condition of the uterus, but it occasionally arises from an affection of the ovarium, or from partial inflammation and suppuration of the peritoneum.

There are sometimes, and only sometimes, sickness and vomiting; there are also, in some instances, a suppression of the lochial discharge, and a flaccid state of the mammæ. But we do not think the precise cases in which these effects do or do not occur, have been distinctly ascertained by the observation of a sufficient number of facts.

In pure puerperal inflammation of the abdomen there is not necessarily much rigor, heat of skin, load of the tongue, affection of the head, or great frequency of the pulse; there is, on the contrary, in many instances, only a slight degree or even an entire absence of rigor, little or no heat of surface, or whiteness of the tongue, little frequency of the pulse, and no affection of the head. But the countenance, manner, and respiration, usually become highly characteristic.

Puerperal inflammation within the abdomen is marked by an expression of extreme pain and anxiety in the countenance; the brow is contracted, and the upper lip is drawn upwards in a peculiar and characteristic manner, and bound round the teeth or rather gums. These appearances are increased on pressing upon the abdomen, or they are observed at that moment if they had not been manifest before. The countenance is generally pale and rather sunk, but with partial heats.

The manner of the patient is much changed, and has become expressive of suffering and anxiety. The movements of the body are attended by pain, and are therefore suppressed; or if performed at all, it is with an expression of suffering in the countenance, and of caution in the manner; and there is an appearance as if the body had become heavy and helpless.

The respiration becomes rather hurried and anxious, and it is performed principally by movements of the thorax, those of the diaphragm and abdomen being more or less, sometimes completely, suppressed,—a circumstance which gives great peculiarity to the appearance of the breathing. Sometimes there is considerable heaving of the chest, with some hurry, some noise from the ingress and egress of the air, and sometimes with a sort of blowing: this state of the respiration is attended by the utmost danger, being frequently one of the first symptoms of the sinking state, of which we shall have to speak immediately, and to which we wish earnestly to call the attention of our readers.

The general surface is usually a little increased in its temperature, and there is frequently perspiration.

The pulse is at first only moderately frequent, but gradually becomes more so, and it is often small and apparently feeble.

We have already alluded to the occasional occurrence of sickness and vomiting. The abdomen is frequently tense and tumid, as well as tender under pressure: this is an affection to be anxiously watched; it sometimes increases to a state of complete tympanitis. The state of the bowels is very various; there is by no means always constipation; sometimes there is diarrhœa, with or without the discharge of mucous stools.

Instead of general tumidity of the abdomen, there is frequently a distinct tumour with tenderness in the region of the uterus, in the iliac region, or in some other region of the abdomen, leading to the suspicion of an especial affection of the uterus or ovarium, or of a partial inflammation and suppuration of the peritoneum.

We have thus described the most usual form of puerperal inflammation of the abdomen in its commencement. It does not seem either possible or profitable to divide the disease into distinct

stages. But it is quite incumbent upon the practitioner to trace the usual changes which are observed in this disease: these are, first, a gradual amendment; secondly, a gradual exasperation of the disease; and thirdly, the supervention of the state of 'sinking.'

Little can or need be said upon the two first of these changes. Every appearance of a return to a healthy state of the functions and general appearances of the patient will raise our hopes; but there are no points of so much importance to be watched as the expression and condition of the countenance, the manner, and the state of the abdomen.

No apparent amendment is to be at all depended upon unless it has continued and been progressive for four-and-twenty hours; this is a caution of great importance to the young physician, in guiding him in his expressions in regard to the prognosis. And even in the most favourable cases the further progress towards recovery is to be watched with the utmost care and precaution.

In the less favourable cases the countenance becomes more and more altered, the pulse more and more frequent, the abdomen more tender and tumid; the muscular powers of the patient appear overwhelmed; the respiration becomes more heaving, and, as we have usually termed it "blowing," being somewhat audible, — a condition of the breathing always attended by the utmost danger. At this period, too, there is often some degree of delirium, alternating perhaps with slight dozing, and there are generally restlessness and jactitation, and the patient cannot bear the arms to be covered.

At this period, too, the tongue is frequently loaded and more foul, and sometimes dry; the bowels are variable, frequently flatulent and loose. The mammæ are flaccid, the lochia suppressed; the skin is clammy and wet, if not cold; the hands and wrists are often livid, and the feet cold.

This description of symptoms applies to the case of general inflammation of the peritoneum. The more partial cases of peritonitis continue longer, and affect the constitution less and less rapidly. In some instances the integuments over the seat of the inflammation have become tumid and inflamed, and an issue has at length been effected for the subjacent pus; the abscess has afterwards collapsed and healed, and the patient has slowly but finally recovered. This opening frequently takes place about half-way between the umbilicus and spinous process of the ilium. In other instances the matter has been evacuated by the rectum, and in some rare examples by the bladder. In other cases the abscess has not been evacuated during life; but the patient has become gradually emaciated, and the health and strength have failed; there have been great frequency of the pulse and hectic, and the disease has at length, though perhaps very slowly, proved fatal. It has, however, occasionally happened that the effused fluid has been re-absorbed, and the fatal event averted.

But the acute form of puerperal peritonitis sometimes issues in a state of sudden sinking of the vital powers. The change and symptoms are such as have frequently led to the suspicion of gangrene having taken place; but no such appearance is observed after death.

This state of sinking is usually rather abrupt in its manifestation. The patient may be left not without hope the preceding night, but on being visited on the ensuing morning is found to have passed into a state of hopeless sinking. The pain has ceased, but the tumidity of the abdomen is augmented; the breathing is attended by heaving and blowing; the skin of the arms and hands is cold, clammy, and livid, the livid colour only partially disappearing on pressure; the pulse is thready and excessively frequent; the countenance is altered and sunk; the patient may be roused, but is then, perhaps, unconscious of pain, and expresses herself as being relieved; the hands are kept out of bed; sometimes there is cough, and the feet are livid and cold.

The morbid appearances usually induced in cases of inflammation of the uterus and of the peritoneum are well known.

In inflammation of the uterus there are, in different instances, exudations of serum, of coagulable lymph, and of pus, or it is the seat of distinct abscesses; and its internal surface is frequently morbidly red, and the source of various discharges. The appendages of the uterus are frequently the seat of similar morbid appearances.

The peritoneum when inflamed pours out serum, coagulable lymph, or pus; and its different surfaces are apt to be variously glued together. Frequently the intestinal canal is found distended to the utmost, as before death, by fetid gases.

In some instances pus is effused and deposited in various parts of the peritoneum, being confined by the adhesion of contiguous portions of this membrane.

There is no part of the peritoneum, and no viscus in the abdomen, which may not become the seat of puerperal inflammation and of the consequent changes of structure. The parts most frequently affected by puerperal inflammation, however, are the organs contained within the pelvis, — the uterus, its appendages, the rectum, the bladder, and the peritoneal lining of the pelvis; and then the peritoneum in general. In an interesting case, published by Dr. Ley, the spleen was found to be a principal seat of disease.

We now proceed to state the treatment of puerperal inflammation, and we must observe, in the first place, that nothing can be trusted to to save the patient but the most ample bloodletting, and in the second place, that nothing should preclude the use of this remedy but the actual existence of the state of sinking.

In regard to the measure and the repetition of the bloodletting, many points must be taken into consideration. The earlier and the more fully this remedy is employed, the more efficacious and the safer it is, and the safer is its full repetition.

There is one point which we would particularly impress upon our readers. It is, that the bloodletting should in this disease always be performed when the patient is in the erect position; and it may then in general be safely carried to deliquium. We do not recommend this mode of proceeding with the view of producing deliquium merely, but also that this deliquium may serve

us as a guide in judging of the extent to which we may carry the depletion. If the patient be sitting upright, and faint by the loss of blood, we have a security and remedy against any danger from this event in laying the patient low; but if deliquium be induced by bleeding the patient in the recumbent position, we cannot say that we think it will be always without danger. We think the plan which we have proposed at once far more safe as well as far more efficacious in subduing this disease. If it were requisite, the patient's head might be laid even lower than the rest of her body, should deliquium supervene.

The same rule may apply for the repetition of the bloodletting. If the fullest effect is desired which the patient can safely bear, let her be bled to syncope in the erect posture. She will faint from losing a larger or a smaller quantity of blood precisely in the inverse proportion of the previous exhaustion; the state of syncope will not only warn us to desist from drawing more blood, but will arrest the flow of blood itself just at the point when the patient can bear to lose no more.

This is a most important criterion for the employment of a most powerful remedy. We do not by any means wish it to be understood that it is always safe to bleed to deliquium in the erect posture; but that, when it is determined to bleed, it is important to have the boundary, which it would be unsafe to pass, at least clearly defined.

Sometimes the patient will faint on being merely placed upright; is it then, ever, and in what particular cases, safe to bleed?

The next question is in regard to topical bloodletting, and we think there is one important rule for the adoption of this remedy. It may of course be enjoined to be done immediately after general bloodletting; but it is particularly useful in those cases in which the system is obviously subdued by the general bloodletting, and yet the inflamed part remains tender under pressure. In such cases leeches, or, still better, cupping, if it be properly and tenderly performed, will prove a most useful remedy.

It is quite unnecessary to state the utility, or rather the necessity, for the administration of purgative medicines in this disease. There is good reason to suppose that some cases have been subdued even by this remedy alone; and the efficacy of purging in conjunction with bloodletting is quite undoubted. A constant catharsis should be kept up, indeed, until the disease is completely subdued.

In cases in which there is great tympanitic distension of the abdomen, an injection of warm water sometimes succeeds in inducing evacuations of flatus, which greatly relieve. We have sometimes thought that still more effectual relief of the same kind might be obtained by the introduction of a flexible tube, properly pierced, high into the large intestine.

Much and important relief may also be afforded in some cases in which suppuration has taken place, by giving exit to the pus when it plainly fluctuates and approaches the surface.

Blisters are also of great service in those cases of this disease which are not attended by much heat or irritability; but in other cases they have appeared to us to add to the patient's sufferings, to prevent sleep, and to do harm by leading to a state of exhaustion.

There are still three other powerful remedies of which a cursory mention must be made in this place. The first is vomiting, which is well known to have been so successful in the hands of M. Doulcet of Paris. The second is the spiritus terebinthinæ, recommended by Dr. Brenan of Dublin. The third is the attempt to induce a state of ptyalism by mercurial medicines and inunctions.

Emetics, like purgative medicines, but especially the spiritus terebinthinæ, have doubtless been used successfully in many cases; but we much suspect that many of these cases were not inflammation, but intestinal irritation.

Ptyalism would seem to deserve a trial; it is one of those measures which are most powerful, and yet generally unattended with risk, and it would by no means preclude the adoption of every other more prompt and efficient mode of treatment. If adopted early, it might prevent some of those protracted states of the disease which occasionally occur and wear out the patient.

During the existence of inflammation the patient should be allowed absolutely nothing but tea or gruel in the smallest quantities.

In some cases in which the pain is not severe, but the tension of the abdomen great, continued but extremely light frictions of the abdomen have done great good. They may be followed by the application of a cold lotion and by fomentation of the feet.

In cases of pure inflammation the use of opium is not desirable. The pain must be subdued by bloodletting; and every thing that by masking the pain can divert our minds from the use of this remedy involves danger to the patient. And there are seldom those symptoms of constitutional irritation which require the use of opium until the inflammation has subsided. In mixed cases we think the use of opium, especially after bloodletting, may be both necessary to subdue constitutional irritation, and beneficial in the cure of the disease. [Under Peritonitis and Narcotics, the value of opium in this and similar phlegmasiæ has been fully investigated.]

Of the effects of Stomachal and Intestinal Irritation.—Some of the effects of intestinal irritation may be observed before parturition; but it is far more usual to find them developed afterwards. They generally take place rather suddenly, about forty or fifty hours after delivery; but the puerperal state appears so to dispose to this affection that the presence of any cause of stomachal or intestinal irritation cannot always be borne with impunity for many days even after delivery.

This affection may, for the facility of description, be divided into the acute and the insidious; each of these forms manifests itself with general symptoms only, or with some predominant local affection.

The acute form of intestinal irritation is generally ushered in by a violent rigor. This is an important fact; for rigor, as we have already observed, has been considered as denoting puerperal inflammation, and essential to the latter disease.

Neither of these suppositions is true; for puerperal inflammation may occur in a severe and fatal form without rigor; and the severest rigor may only portend an attack of the effects of intestinal irritation; and in general the latter disease is attended even with a severer rigor than the former.

In the attack of intestinal irritation there is usually, after the rigor, great heat of the surface. We have already observed that this is by no means an essential part of puerperal inflammation; indeed we do not think that it properly belongs to the latter disease, but that, when it does occur with inflammation, it denotes a mixed case and the coexistence of intestinal irritation.

In the attack of the effects of intestinal irritation there is usually earlier and even greater frequency of the pulse than in cases of puerperal inflammation; the pulse is also usually fuller than in the latter disease.

Intestinal irritation induces symptoms which are similar to those of the most acute phrenitis, or to those of the most acute peritonitis. This is a remark of the utmost practical importance; for the remedies in these different cases are totally different; and we should say that in the former the freest bloodletting must be aided by purgative medicines, whilst in the latter the freest and fullest evacuation of the intestines must be aided by bloodletting.

A mistake in either case would, in our opinion, endanger the life of the patient; and it is a foolish and idle remark to say that it is better to mistake irritation for inflammation than inflammation for irritation. It is of the utmost importance to attend to the distinctions which we have made between inflammation and intestinal irritation in regard to the treatment; for, although both bloodletting and purging are to be used in every case, yet the former is the remedy in inflammation, and the latter in intestinal irritation. If the cure of inflammation be trusted even chiefly to purgative medicines, we think it will frequently proceed to the destruction of the patient; and if bloodletting should be chiefly employed, in like manner, in intestinal irritation, we believe it would leave the disease unsubdued, and eventually plunge the patient into a state of irremediable exhaustion.

The affection of the head and that of the abdomen frequently coexist or alternate in the same case; but sometimes one of them exists to the exclusion of the other, or supervenes upon the cessation of the other; and in the latter case the affection of the head usually succeeds that of the abdomen. The diagnosis is much confirmed by this conjunction of the two affections.

In the affection of the head from intestinal irritation there is frequently the severest pain and the utmost intolerance of noise, light, and disturbance of every kind. It is in these cases principally that the pavement is covered with straw, the knocker tied, the patient's room kept dark and still, so that these very external circumstances speak a significant language to the physician. To the symptoms which have been enumerated are frequently added wakefulness and even delirium.

When the abdomen is affected from intestinal irritation, there are general pain and tenderness upon pressure, and frequently tumidity, combined with the general symptoms which we have already enumerated.

Much is effected and learnt in this case by the exhibition of large injections of warm water and of active purgative medicines, a careful examination of the evacuations, and a studious observation of the effects produced upon the disease. The fæces will be found to be scybalous, or at least offensive and dark-coloured, and in large quantity; and the relief obtained, or the return of pain, will be found to depend upon the evacuated or neglected state of the bowels.

Another point of great importance is an attentive inquiry into the diet of the patient; this inquiry frequently reveals the mystery of an attack, and of course immediately leads to the adoption of an important remedy.

In regard to the course of cases of intestinal irritation, we imagine that under judicious treatment this would always be one of progressive recovery. When a contrary event occurs, we think it is to be attributed to the misuse of remedies, and especially of bloodletting. In this manner some of the symptoms which are detailed in the succeeding section are superinduced, and sometimes a sudden dissolution has overwhelmed the practitioner with consternation.

One of the characteristics of intestinal irritation is the susceptibility to syncope upon bloodletting. This is of course much more remarkable upon a second or third bloodletting than upon a first use of the lancet. No dependence can be placed upon the appearance of the blood drawn. This may be much buffed and cupped in the puerperal state without the existence of inflammation, and in cases of the most decided inflammation these appearances of the blood may be but little observed.

We have scarcely had an opportunity of examining the state of the internal organs after death; for in general the patients affected by intestinal irritation have recovered. But no doubt that such an examination would illustrate the following important remark of the late Dr. Denman: —"We have been told that in the dissection of some who are said to have died of puerperal fever, no appearances of inflammation have been discovered; but I should suspect that in such cases some important appearances had been overlooked, or that errors had been committed as to the nature of the disease, and probably in its treatment." A due consideration of the effects of intestinal irritation will also serve to elucidate other cases of morbid affection, in which the appearances of inflammation were looked for on dissection, but were not found. This observation applies particularly to affections of the head, heart, and abdomen. In several cases of this morbid affection, which we had the opportunity of examining many years ago, no morbid appearances were found on the most careful inspection. We have already sufficiently alluded to the causes of this affection. They are for the most part obvious sources of gastric or of intestinal irritation; the former chiefly affecting the head, the latter both the head and the abdomen, either together or separately.

In the treatment of the effects of intestinal irritation, we would by no means exclude the use of the lancet. Bloodletting may be useful in such a case, for the same reason that it is useful in simi

ple fever. But we repeat that this remedy is only subsidiary to the full and free evaeuation of the bowels, and, if necessary, of the stomach. If it were trusted to alone, or with only a moderate attention to the state of the alimentary canal, or if it were used in the manner which is required to be effieient in puerperal inflammation, we are persuaded that the patient would die of exhaustion, before the symptoms would yield.

The remedies of intestinal irritation and its effects we would enumerate and arrange in the following order: — first, the full evacuation of the intestinal canal; secondly, bloodletting; thirdly, some soothing anodyne; fourthly, leeches, cupping, a lotion, a liniment, or a blister, acecording to the circumstances of the case, for the topieal affection; fifthly, the mildest nutritious food; sixthly, the most absolute quiet, and the most perfect security from light, noise, disturbance, and every other source of excitation; seventhly, great coolness, and free ventilation of the sick-room; and lastly, a constant watehing over the patient during sleep, to avoid the injurious effects of turbulent dreams on the one hand, and of too long sleep and fasting on the other. Upon eaeh of these points we proceed to make such observations as we have learnt from practiee to be of importance.

In regard to the state of the alimentary canal, it is quite obvious that an emetic is the proper remedy when the symptoms can be attributed to any indigestible substanee taken; and we would recommend this remedy, even although it might appear, from the lapse of time, unlikely that the injurious substance should still remain in the stomaeh.

When the case originates from intestinal irritation, we would earnestly recommend that the first remedy should be an enema, consisting of three or four pints of warm water, very slowly and gently forced into the bowels. This should be followed by an active purge; and this should, in due time, be followed by a repetition of the injeetion. The evacuations should be immediately carefully examined, and the effects upon the symptoms of the disease be watched.

To abate the general heat and excitement of the system, to relieve the head or the abdomen, and to ensure perfect safety, the patient should, in cases in which the strength is not particularly impaired, be raised into the erect posture, and be blooded until faintishness be induced. This effect, also, should be carefully watehed and observed. If it oecur from the loss of a small quantity of blood, it confirms the diagnosis; if it do not occur until mueh blood have flowed, it should suggest the suspicion of more than mere intestinal irritation,—of one of those mixed cases which so frequently oeeur, and of which we propose to treat in a subsequent seetion.

We do not imagine that this decided use of the lancet can ever be attended with danger, if there have been no previous loss of blood or other cause of exhaustion. But it could not be repeated with impunity. It would lead to exhaustion with the symptoms of reaction, to the state of sinking, or even to sudden dissolution; and if the case be really one of intestinal irritation, and the other remedies have been duly applied, such repetition of bloodletting will not be required.

It is an observation of great importance, that in inflammation repeated bloodletting is required, and is borne with safety; in intestinal irritation, on the contrary, the repetition of bloodletting is nei ther necessary nor safe.

This free evacuation of the bowels and detraction of blood are very apt to be followed by symptoms of hurry and alarm in the system. These effects are frequently prevented by the timely administration of an efficient and kindly anodyne; and we believe no anodyne is possessed of those qualities in a higher degree than Battley's *liquor opii sedativus*. Of this excellent medicine a full dose may be given, and, if necessary, repeated in five or six hours.

If this plan do not perfeetly relieve the topical affection, some loeal remedy must be applied. In cases of ecrebral affection, leeches may be applied to the temples, or cupping, or a blister, to the nape of the neek, a cold lotion over the whole head, and fomentation to the feet. Leeches, a fomentation, a liniment, or a blister may be applied, if there be affection of the abdomen.

Before the patient falls asleep, we should recommend some mild food to be taken, as gruel or panada. This plan prevents exhaustion, and frequently relieves the local symptoms by securing a more refreshing kind of sleep. For the same reason the utmost quiet must be preserved in the patient's room. The least disturbance greatly agitates the patient, and prevents the good effects of the remedies which have been employed.

Some other circumstances have been before enumerated which claim our attention in the treatment of this morbid affection; but, in order to prevent repetition, we postpone the remarks which we have to make upon these points to the next seetion,—upon the effeets of loss of blood; in which case an attention to them is, if possible, still more neeessary than in that under our immediate consideration.

On the Effects of loss of Blood in the Puerperal State.—The effeets of loss of blood usually present themselves to our notiee in rather an insidious manner; they are not generally introduced by rigor, or heat, or any other acute symptom; though there may be exceptions to the last part of this rule. It is an important remark that the remoter effects of loss of blood are frequently developed in cases in which there is also intestinal irritation in a dormant form, but that they very rarely occur in conjunction with inflammation; the effects of loss of blood, when they do oeeur in cases of inflammation, generally denote that the inflammatory action has been subdued.

We have already observed that there is rarely either rigor or heat of surface: there may be transient chills and flushes, and slightly augmented temperature; but the eountenance, and especially the prolabium, is generally pallid, and the skin is in a natural state.

The case is usually denoted by a throbbing fulness with moderate frequency of the pulse, throbbing pain of the head and palpitation of the heart, which is apt to alternate with a state of syncope on slight exertion, or on assuming the erect pos-

tune; and there is usually a degree of panting. There is a characteristic susceptibility to fainting on taking a very small quantity of blood.

We have repeatedly known the effects of loss of blood to be mistaken for inflammation of the brain on one hand, and disease of the heart on the other. We consider this an important remark, as suggesting at once two characteristics of this affection, and the necessary caution in the diagnosis in puerperal diseases.

When the head is affected from loss of blood, there are much beating and throbbing of the temples, pain, a sense of pressure, or vertigo, with rushing or cracking noises.

When the heart is affected, there are great fluttering, beating, or palpitation, starting during sleep, hurry and alarm on awaking, sometimes with faintishness, a feeling of sinking or of impending dissolution, &c., and with the palpitation there is frequently beating and throbbing of the carotids, and sometimes of the abdominal aorta, perceptible to the touch or even to the eye. These affections sometimes recur in the form of attacks which are attended by much hurry and alarm.

Besides these more marked affections of the head and heart, which render it so necessary to distinguish this affection from inflammation or disease of those organs respectively, there are many symptoms which occur in a less marked degree or form.

There is frequently an inability to bear noise or disturbance, or even the act of thinking with attention; but there is rarely intolerance of light; the last symptom usually denoting a state of intestinal irritation.

There are frequently vertigo or faintishness on any exertion, or on assuming the erect posture; and when these two are combined, there has sometimes been a sudden and unexpected fatal termination of the patient's sufferings. In many cases there are great faintishness and urgent demand for the smelling-bottle, for the fan, or the fresh air, and for cold applications to the face or temples, and a feeling of impending dissolution. The respiration is affected in different cases with panting, hurry, sighing, heaving, blowing, moaning, gasping, catching, &c. There is in some cases an irritative cough in violent fits, or in the form of perpetual hacking, apparently arising from an affection of the larynx or trachea. The stomach is liable to be affected with retching, vomiting, hiccup, and eructation; and the bowels, even in cases in which they were not previously disordered, become variously deranged, with constipation, diarrhœa, and flatulency. There are frequently, in severe cases, urgent restlessness and jactitation. In some cases there are various spasmodic affections. In other instances there are catching pains, which are apt to be mistaken for inflammation. There are frequent changes, sudden attacks of alarming symptoms, a sense and fear of impending dissolution, urgent messages, &c., which become characteristic of this affection.

Another characteristic consists in the faintishness, gasping, or feeling of dissolution, which sometimes follows even a slight bloodletting; an awfully sudden death has immediately ensued upon a full and mistaken bloodletting at this critical period. Even the operation of purgative medicine has sometimes induced a degree of faintishness.

Every source of disturbance, of anxiety, or of alarm, and every kind of effort either of mind or body, is apt to be followed by a return or exasperation of the symptoms, and cannot be said to be free from danger. We have already remarked that an effort of the muscles and assumption of the erect posture have proved suddenly fatal. This sad event occurred to a lady who raised herself in bed in this exhausted state to make water; she fell down and expired. But when the fatal event from loss of blood is not sudden in this manner, the state of reaction sometimes yields to one of fatal sinking.

The symptoms of exhaustion with excessive reaction may gradually subside and leave the patient feeble, but with returning health; or they may yield to the state of sinking. This term is adopted not to express a state of negative weakness merely, which may continue long and issue in eventual recovery; but to denote a state of positive and progressive failure of the vital powers attended by its peculiar effects, and by a set of phenomena very different from those of exhaustion with reaction.

If in the latter the energies of the system were augmented, in the former the functions of the brain, the lungs, and the heart are singularly impaired. The sensibilities of the brain subside, and the patient is no longer affected by noises as before; there is, on the contrary, a tendency to dozing, and gradually, some of those effects on the muscular system which denote a diminished sensibility of the brain supervene, as snoring, stertor, blowing up of the cheeks in breathing, &c.; instead of the hurry and alarm on waking, as observed in the case of excessive reaction, the patient in the state of sinking requires a moment to recollect herself and recover her consciousness, is perhaps affected with slight delirium, and is apt to forget the circumstances of her situation, and, inattentive to the objects around her, to fall again into a state of dozing.

Not less remarkable is the effect of the state of exhaustion with sinking on the function of the lungs; indeed, the very first sure indication of this state is, we believe, to be found in the supervention of a crepitus in the respiration, only to be heard at first on the most attentive listening; this crepitus gradually becomes more audible, and passes into slight rattling, heard in the situation of the bronchi and trachea; there is also a degree of labour or oppression, sighing, hurry, and blowing, in the breathing, inducing acuteness in the nostrils, which are dilated below and drawn in above the lobes, at each inspiration; in some cases there is besides a peculiar, catching, laryngeal cough, which is especially apt to come on during sleep, and awakes or imperfectly awakes the patient. The heart has at the same time lost its violent beat and palpitation, and the pulse and arteries their bounding or throbbing. The stomach and bowels become disordered, flatulent, and tympanitic, and the command over the sphincters is impaired. The last stage of sinking is denoted by a pale and sunk countenance, inquietude, jactitation, delirium, and coldness of the extremities.

We now propose to detail the principles of the

treatment in cases of the effects of loss of blood in the puerperal state.

In the first place the state of exhaustion from loss of blood, with or without reaction, by no means precludes the possibility of congestion within the head; and it is no less certain that the application of leeches to the temples, or of the cupping-glass to the back of the neck, relieves the symptoms of affection of the head, arising from loss of blood, in a remarkable manner. In a case given by Mr. Hey, which we regard as being of this character, and to which we shall have occasion to revert hereafter, urgent symptoms of affection of the head were twice relieved by the abstraction of but three ounces of blood from the temporal artery. This mode of treatment must not, therefore, be neglected except in the most extreme cases, in which the loss of even so small a quantity of blood, and that from the head even, might prostrate the remaining powers of the patient.

The next point of practice which requires to be mentioned is the state of the stomach and bowels. If these were free from all disorder before the occurrence of the loss of blood, yet the state of exhaustion ever induces a deranged state of the alimentary canal. The state of the bowels must, therefore, claim our attentive consideration in every case of symptoms arising from loss of blood. Their functions and tone must be carefully restored by every means in our power, while we as carefully avoid any fresh source of exhaustion. The bowels must in particular be carefully evacuated daily. This may perhaps be best done by means of the warm-water injection so often recommended by us already, with or without the aid of a draught containing an ounce of the infusion, and two or three drachms of the compound tincture of rhubarb, and of manna.

By these means the state of irritability which is so apt to affect the system, and especially the head and the heart, in cases of exhaustion from loss of blood, is greatly obviated. But for this affection it is frequently also necessary to give some mild but efficient anodyne. The tinctura opii, the tinctura hyoscyami, the spiritus ammoniæ aromaticus, &c. are extremely useful remedies in this affection. But perhaps the best are Battley's liquor opii sedativus, or the extract of poppy, given in efficient doses.

When the head, the heart, and the alimentary canal have been thus relieved, and even during the exhibition of the medicines which have been enumerated, it is of the first importance to attend to all the following points: viz. nourishment, fresh air, quiet, soothing, sleep, &c.

It is difficult to give fixed rules for the administration of nourishment; but the first rule is to ascertain that the bowels have been properly evacuated, otherwise food will only oppress the stomach; the second is to give the nourishment itself in such forms as will prove light and easy of digestion; the third is that it should be taken at first very slowly and in small quantities. Arrow-root in water, beef-tea, panada, sago, &c. may be given frequently.

The best restorative we possess is, we believe, fresh air; but it is especially the best in the cases under consideration. The warmth and closeness of a lying-in room must therefore be forthwith exchanged for free ventilation, only observing the due precautions against giving cold.

Nothing is more essential than quiet both of body and mind. Bodily exertion leads to still further exhaustion, and perhaps even to unexpected dissolution; and every kind of mental effort or hurry not only exhausts the patient's strength, but is extremely apt to lead to those attacks of symptoms of irritability of which we have given so full a description.

The patient should be soothed and lulled in every possible way; and it is of the utmost importance to procure sleep. But it should be observed, in regard to sleep, that too long a sleep is apt to exhaust or overwhelm the patient. This is especially true if it be not preceded by nourishment. The sleep is also apt to be injurious by leading to turbulent dreams, which have the same bad effects as waking hurry of mind; the sleep should, therefore, be watched, and it should be interrupted if the patient is observed to suffer from agitation: this is best done, we think, by offering nourishment, for the patient is immediately collected, on awaking, from knowing what is doing.

There is one point which we have not hitherto mentioned as it deserves; it is the efforts made by the patient to suckle her infant. Nothing is so injurious in all puerperal diseases. These morbid affections have often appeared to be first induced by the attempt to nurse; and they have still more frequently been exasperated by it. This attempt especially involves within itself almost every thing which can be injurious in a state of exhaustion; the drain, the muscular effort, the mental excitement implied in the act of suckling, are all of the most injurious tendency in this affection.

Of mixed cases, and especially of Puerperal Mania. — Perhaps the cases which most frequently present themselves to our notice in practice are of a character distinct from those which have been described in the preceding sections, differing from them principally by blending two or all three of those cases in an individual patient.

Our systems of nosology have, we are persuaded, greatly erred in attempting to separate diseases from each other, and describe them as distinct, when they far more frequently occur in conjunction; so that the mind of the medical student is not at all prepared for the cases which most frequently occur to him when he first enters upon practice. A little experience teaches him the difficulty, nay the absurdity, of attempting to give each individual case a name, or to put it down in a list of diseases. Each patient, on the contrary, presents to him a new congeries of symptoms, a new complication of diseases or disorders.

To apply these remarks to our present subject, it may be truly said that puerperal cases are more complicated than any. But we have already insisted upon this point; and we now proceed to illustrate the various combinations of inflammation with intestinal irritation, or of either or both, with the effects of loss of blood.

Some cases have conjoined the most decided symptoms of intestinal irritation with those of in-

flammation, and, having proved fatal, have presented all the traces of inflammatory action on examination. It has already been shown that in many cases of inflammation there are none of the symptoms which denote intestinal irritation; there is an absence of rigor, of heat, of affection of the head, &c.; but the effects of inflammation are found upon dissection. On the other hand, there have been all the symptoms of intestinal irritation, as rigor, heat, headach, with pain, tenderness, and tension of the abdomen, without a trace of the effects of inflammatory action on examination after death. The conclusion from these separate statements is obvious; inflammation and intestinal irritation may exist separately, but they may also exist together.

The effects of loss of blood are frequently observed in cases of inflammation, when the primary disease has been perfectly subdued. But they are still more apt to concur and to assimilate themselves with those of intestinal irritation, when there has been much loss of blood by hemorrhage or by bloodletting.

This subject, as well as the interesting question of the diagnosis, might be illustrated by a reference to the valuable treatise of Mr. Hey upon puerperal fever. This author, as well indeed as almost every writer upon this subject, appears to us to have combined in one description all the three different cases of which we have treated. It is not, therefore, wonderful that their works should involve many inexplicable discrepancies in the symptoms and in the treatment. Some cases have occurred without rigor, heat, or headach; others have combined all three with or without affection of the abdomen. Some have been cured without the lancet; others have not yielded to the most judicious and most ample bloodletting. It is doubtless a most important question,—how can these discrepancies be explained?

Other difficulties and other discrepancies have arisen from the addition or superinduction of the symptoms of loss of blood, in cases of inflammation or of intestinal irritation. This is a mixed case which frequently occurs, and causes much embarrassment to the young and inexperienced physician; and it has too frequently happened that the lancet has been prescribed under a false impression of inflammation; and that great danger and even immediate dissolution have ensued.

There is a mixed case which shows itself under a still different form from any which have hitherto been described; it is *puerperal mania*. We believe this disease to result, in general, from all the circumstances following parturition combined, but chiefly from the united influences of intestinal irritation and loss of blood. We purpose to pursue this subject hereafter. In the meantime, however, we would observe that we are persuaded that real puerperal phrenitis is comparatively a rare disease; that puerperal mania is seldom of an inflammatory character, and that it is especially to be treated by those measures which are suited to the mixed case of intestinal irritation and exhaustion. This opinion is confirmed by the fact of mania occurring from undue lactation, as well as from the circumstances of the puerperal state. We are inclined to attribute much more to the combined influence of irritation and exhaustion than to the mere "state of the sexual system which occurs after delivery," which has been assigned as the chief cause of this morbid affection by Dr. Gooch, in a most interesting paper upon this subject in the sixth volume of the Transactions of the College of Physicians, p. 280; although we would by no means exclude the influence of this principle altogether. There is ample evidence in Dr. Gooch's cases of the influence of intestinal disorder; and the events of labour and the circumstances of lactation ever add to this a state of exhaustion. This view is the more important, because it directly suggests the proper mode of treatment, which consists in restoring the system to a state of due health by every means in our power, whilst we adopt every measure which can soothe and allay the morbid irritability of the nervous system.

We are confirmed in this view of the nature of puerperal mania not only by a careful investigation of its causes and the good effects of the remedies which we have mentioned, but by having met with the symptoms of intestinal irritation as a prelude to those of mania.

There are frequently also many of the appearances of disorder of the general health, sometimes jaundice even; and the state of the complexion and of the alvine evacuations leaves no doubt as to the influence of the morbid condition of the intestinal canal. Bloodletting plunges the patient into a state of danger, perhaps into one of irretrievable sinking.

Puerperal mania is, in fact, in the most emphatic sense a mixed case: previous derangement of the health; intestinal irritation; loss of blood; the pain and shock, and anxiety attendant on parturition; the subsequent morbid state of the genital organs;—all these may combine with predisposition to induce the maniacal attack.

But our attention must be chiefly directed to the degree of exhaustion which obtains, to direct us what remedies to employ and what measures to avoid.

On being called to a case of puerperal mania, we have long been in the habit of asking whether the patient has or has not been bled; on this greatly depends the event of the case: if blood has been freely taken, the patient will probably die; if otherwise, most puerperal cases of mania issue well.

It must be admitted in this place, however, that puerperal mania may possibly be combined with inflammation, especially of the uterus, its appendages, or the peritoneum. This is to be ascertained by a careful examination. In such a case bloodletting must be used, and in such a case it can be borne.

Puerperal phrenitis is certainly a rare disease. This opinion was early expressed by the writer of this article, and it is confirmed by Dr. Gooch. The same remark may be made in regard to the most influential cause of puerperal mania, and the danger of bloodletting in that disease.

The symptoms in puerperal mania occur in the most insidious manner: there is a little excitement during the day, and sleeplessness at night, then something bordering on delirium; then actual delirium; and then confirmed mania.

The most important parts of the treatment are

extreme quiet of mind and of body; a regulated state of the bowels; a mild, light, but nutritious diet; a cold lotion to the head; fomentations to the feet; every soothing plan; careful watching; and time. It too frequently happens that the friends undo in one day what the physician's care has effected in many: visitors intrude; the infant is brought; conversation, excitement are permitted.

The treatment consists, in fact, much more in avoiding sources of harm than in positive remedies. Bloodletting is replete with danger; every depleting means, by adding to the exhaustion, adds to the malady. The cure depends more upon nursing than upon the materia medica. It is proper, however, to state that the mildest opiates have lulled and soothed, and obtained rest, and allayed the disease. The progress of puerperal mania has also been controlled by administering mercury so as to induce ptyalism, and avoiding its effects on the bowels. [See the article Insanity.]

We have thus given a rapid sketch of those puerperal diseases which are of most frequent occurrence and greatest practical interest. But there is another series of puerperal diseases of a still more terrible character, of which a sketch must now be added. They consist of softening of the substance of the uterus, inflammation of the lymphatics, and phlebitis.

The first of these may be suspected whenever there are, after rigors and fever, with uterine pain or tenderness, and suppressed lochia, symptoms like those of the sinking state, the countenance becoming collapsed, the pulse extremely frequent and small, the respiration hurried and anxious, the strength prostrate.

The symptoms in inflammation of the lymphatics are very similar, and of a typhoid character; these are usually conjoined with those of peritonitis, and occasionally with pleuritis. But there are not the secondary abscesses observed in the disease to be next mentioned.

The important distinction in regard to uterine, as in the other forms of phlebitis, is between the adhesive and the suppurative. In the former the effects are localized. Uterine phlebitis of the adhesive character is attended by local pain and tenderness. The occurrence of crural phlebitis seems to constitute the disease formerly termed the phlegmasia dolens. This disease is distinguished by pain in the situation of the iliac and inguinal veins, with tension and swelling, afterwards pursuing their course down the thigh. The femoral vein is white, tense, elastic, painful, and tender.

The suppurative phlebitis is a far more formidable and fatal disease. It is denoted by the occurrence of terrific typhoid symptoms, and by external suppurative inflammation of the integuments or of the eye; whilst abscesses form internally in the brain, the lobules of the lungs and liver, in the spleen, in the joints, in the muscular substance, &c. It is usually unattended by peritonitis.

Of the treatment of softening of the uterus, and inflammation of the lymphatics, and of suppurative and diffused phlebitis, little is known; and it would be foreign to the object of this sketch to enter upon any discussion of the subject.

Marshall Hall.

PUERPERAL FEVER.—See Fever [Puerperal.]

PULSE. — The stroke or beat of an artery, as recognised, for the most part, by the finger applied to the integuments lying over it, is denominated *the pulse*; by the Greeks it was termed σφυγμὸς; by the Latins *pulsus*, whence our English term is derived.

We propose to divide the following article into three parts, which may be regarded respectively as historical, physiological, and pathological. The first will consist of a brief historical account of what was known on the subject of the pulse by the ancients, as well as the opinions that have been entertained respecting it by the moderns. In the second place, we shall inquire into the cause of the pulse. We shall endeavour to explain its different varieties, and shall point out their connection with the other parts of the animal economy. Lastly, we shall offer some remarks on the morbid conditions of the pulse, and inquire into the degree in which they may enable us to judge of the seat and nature of disease, so as to assist us in forming our diagnosis and prognosis, and in directing our practice.

1. History of the opinions that have been entertained respecting the pulse.—We have a distinct notice of the pulse in the writings of Hippocrates; it is mentioned, however, incidentally, and in a few passages only, and he appears to have attached scarcely any importance to it, either theoretical or practical. It is commonly supposed that he is the first writer who employed the term pulse (σφυγμὸς) to denote the natural and ordinary beating of the artery. It would seem that the ancients usually applied the term to what we should call pulsation, i. e. the beating that is felt by the individual himself, in a part that is inflamed, or otherwise morbidly affected, without applying the finger to it. But although there are certain passages in the writings of Hippocrates where the word is used in the more correct and restricted sense, yet it must be admitted that these are few in number; a circumstance which is the more remarkable, when we consider with what minute accuracy he detailed the other symptoms of the diseases of which he has left us a distinct account. We may farther notice, that from the manner in which he refers to the pulse, he seems to have made little or no use of it, either in regulating his practice, or in forming his diagnosis. Where, for example, he gives a detailed account of the phenomena of fever, he states with great minuteness the temperature of the patient, the state of the respiration, of the secretions and excretions, and indeed all the circumstances to which the most judicious modern physician would direct his attention, except the pulse. The only use which Hippocrates made of the pulse was to assist him in forming his prognosis; but even here we meet with little of that acuteness of observation which, on most occasions, characterizes the writings of the great father of medical science.*

It is generally agreed that Herophilus was the first physician who was fully aware of the import-

* Hippocrates enumerates a peculiar state of the pulse among the signs of disease in his treatise 'De Humoribus;' also, in various parts of his 'Coacæ Prænotiones.'

ance of the pulse, and paid particular attention to its various conditions. He was one of the most distinguished ornaments of the Alexandrian school, and is especially celebrated for his knowledge of anatomy, into which science he introduced many great improvements. The fame of Herophilus is principally supported by the authority of Galen, who expressly notices his merits on this point. (See his treatise De Diff. Puls. lib. ii. c. 10.) We learn, however, from Pliny (Hist. Nat. xxix. 1), that he was supposed by some to have introduced into practice a number of unnecessary and even fallacious distinctions concerning the pulse, and that, for the most part, his opinions were derived more from hypothesis than from actual observation.

The author whom we shall next notice is Celsus. The judicious manner in which he treats his subject, the candour which he displays in referring to the opinions of others, together with the elegance and purity of his diction, have caused him to be regarded as one of our highest classical authorities. This is more especially the case on all questions of literary history, as he appears to have aimed more at giving a correct view of the state of medical science at this age, than a mere transcript of his own observations and experience. In his account of the pulse, he has been supposed to revert to the doctrine of Hippocrates. When giving directions for the treatment of fever, he remarks upon the great importance of obtaining a correct criterion of the presence of the disease, and in this connection he introduces the following observation: "We principally trust to the veins, a thing which is most fallacious, for they are frequently too slow or too quick, depending on the age, the sex, and the peculiar nature of the body." He goes on to inform us that there are various cases in which the pulse is affected by circumstances quite unconnected with any morbid condition of the body, and where we should fall into the greatest mistakes were we to suffer our judgment to be influenced by the state of the pulse. (Lib. iii. cap. 6.) The multiplied and varied experience of the modern practitioner has proved that the precautions of Celsus, although not without some foundation, were carried to an unreasonable length; and that, although the pulse is affected by most if not by all the extraneous circumstances mentioned by him, yet that it still leaves us the most valuable indications of the state and nature of disease.

We now arrive at the period of the celebrated Galen, a man whose talents and acquirements were of the first order, and who from other causes obtained an ascendancy over medical opinions more considerable and more durable than had been acquired by any of his predecessors; and we may venture to add, than will be ever again obtained by any individual. There is scarcely any topic, connected either with medicine or pathology, which Galen has not investigated; and the pulse is one on which he bestowed a peculiar degree of attention. He has devoted to this subject no less than six different treatises, some of considerable length, in which he investigates in the most elaborate manner everything concerning the use of the pulse, its causes, its different varieties, the method of distinguishing these varieties, the prognostics to be deduced from them, and other analogous subjects.*

A characteristic feature of the writings of Galen is the methodical arrangement, and the numerous technical divisions which he introduces into almost all the subjects which fall under his notice. He proceeds on this principle when treating of prognostics, which he classes under the three heads of those which relate to the concoction of the humours, to the absolute removal of the disease, or to particular crises of various kinds. Again, he supposes crises of all kinds to be derived from three kinds of powers or actions, arranging them, according to their origin, under the denominations of natural, vital, or animal; the pulse he regards as principally indicative of the different kinds of vital actions. It would carry us far beyond all reasonable limits, were we to follow our author into his speculations concerning the causes of the pulse, and the mode in which its different actions manifest themselves, so as to give rise to a most complicated system of minute distinctions and varieties, which it is difficult even to comprehend, and of which few only have probably any actual existence.

With respect to the cause of the pulse, Galen, according to his ordinary custom in such cases, attributes it to a specific faculty, inherent in the heart and vessels, which he names pulsative, by which their alternate contraction and dilatation is produced. As the pulse is an effect resulting from the action of the vital faculties, it affords us one of the most correct indications by which we may judge of the strength or weakness of the vital powers in general, and of the consequent tendency to life or death, and thus constitutes one of our most valuable means of prognosis. Hence the extreme importance of making ourselves acquainted with all its variations, and connecting them with the state of the other actions and functions of the animal economy.

The use of the pulse was supposed to be to maintain the heat of the body, and to remove the excess of excrementitious matter from the blood; by considering the condition of the vital powers, in relation to these supposed processes, he lays the foundation for the differences in the pulse which he endeavours to establish. These differences he first arranges under the two heads of simple and compound, which he again subdivides into numerous varieties, depending partly upon the supposed quantity of motion in the vessels, the nature of this motion, the length of time which it occupies, the space which intervenes between the pulsations, the force of the vital action, and the particular disposition of the artery. Proceeding upon these principles, he forms all the supposable combinations of these different circumstances, and from them he deduces a great number of varieties, to which he gives distinct appellations, but which it would be useless to attempt to describe, or even to enumerate.

Those who are curious to obtain farther information on this point may especially consult his dissertation "On the Varieties of the Pulse," a work

* The following are the Latin titles of Galen's Treatises on the Pulse: De Pulsuum Usa; Introductio in Pulsus; De Differentiis Pulsuum, 4 lib.; De Cognoscendis Pulsibus, 4 lib.; De Causis Pulsuum, 4 lib.; De Præcognitione ex Pulsibus, 4 lib.

of considerable length, which is exclusively devoted to this particular object. It may be regarded as one of the most learned of Galen's performances, and as peculiarly characteristic of the methodical and technical manner in which he treats his subjects.

After the age of Galen we have little to detain us until the revival of medical science by the Italians in the sixteenth century. Medicine was, indeed, very assiduously cultivated by the succcssors of Galen, during what are termed the dark ages; and among the Arabs especially, we meet with various individuals of great eminence for their learning. But their attention was almost entirely confined to the writings of the Greeks, and particularly to those of Galen, which they regarded as standards of excellence; these they translated and republished in various forms, and illustrated by almost innumerable commentaries and dissertations, adding very few original observations, and making scarcely any advance in the principles of the science. This system prevailed to so great an extent, that it has been asserted, and, as it would appear, without exaggeration, that for more than one thousand years after the death of Galen, scarcely a single improvement in medicine or physiology was made which has been thought worthy of being transmitted to posterity.

In tracing the history of science among the nations of antiquity, we seldom think it necessary to go beyond the limits of Europe, or the period of Grecian literature; yet it is generally admitted that the Greeks were not themselves the inventors or the originators of the arts in which they so much excelled. It is a question of very difficult decision, what was the country in which they took their rise, whether in Egypt or in India, or in some other part of the East. It is, however, certain that the Oriental nations made very early advances in various departments; and that, while Europe has been undergoing numerous revolutions, and been gradually advancing to its present state of improvemcnt, Asia has remained much more stationary; so that, in many cases, we have reason to believe that it exhibits at this day nearly the same condition which existed perhaps two thousand years ago. This is most remarkably the case with the Chinese, both in regard to their early civilization and to the little change it has experiencced; and it hence becomes a subject of great interest and curiosity to inquire into the opinions and practices of this remarkable people.

We are furnished by the missionary Jesuits with a minute account of Chinese medicine, and particularly of their opinions respecting the pulse. It appears that they paid great attention to it, and supposed that it afforded them indications of almost every change to which the body is subject, as well salutary as morbid. Thus, among other notions, it was conceived that the different organs produced by their derangement different effects upon the pulse, some of which were to be detected by examining the pulse of the right side of the body, and others that of the left. They farther imagined that from the state of the pulse of a pregnant woman, the sex of the fœtus might be ascertained. They arranged the different parts of the body under three divisions, upper, middle, and lower, in conformity with their respective situations; and they conceived, that according as one or other of these parts was affected, so a corresponding state of the pulse was to be recognised. (See especially the "Description de la Chine," by Du Halde.) We might be the more disposed to inveigh against the futility and absurdity of these opinions, were we not aware that they but too much resemble some of those which were supported by the most enlightened and learned physicians of Europe scarcely a century ago.

At the revival of letters, when the human intellect began to rouse itself from its long repose, the mathematical sect of physicians sprung up. Their reasonings were, for the most part, founded upon erroneous principles, and were almost exclusively derived from physical deductions, which were inapplicable to the phenomena of the living body. Still these labours were not entirely without their use, by stimulating the mind to exertion, and by indirectly leading it to those subjects which are more connected with the principles that ought to guide us in our inquiries. It is on this account chiefly that we notice the name of Bellini, a learned professor of Pisa, who flourished in the beginning of the seventeenth century, and wrote a treatise on the pulse. (De Urinis et Pulsibus, 1683.) Although the fundamental principles of the sect to which Bellini belonged were, in many respects, essentially erroneous, yet they led to a closeness of reasoning which was more favourable to the progress of knowledge than the completely hypothetical method of their rivals the chemists.

It was not, however, until the immortal discovery of Harvey was generally recognised, and its importance duly appreciated, that any considerable progress could be made in our knowledge of the laws of the circulation, or that we could expect to form any just conception, either of the theory of the pulse, or of the circumstances that might be supposed to affect it. The general turn for observation which now became prevalent in all the departments of philosophy, of which the discovery of Harvey itself may be regarded as one of the most splendid results, gave rise to various investigations respecting the cause and nature of the pulse, varying much in their respective merits and importance, but all of them professing to be derived from observation or experience, and contributing more or less to the establishment of the principles of a correct theory.

Among the first of these productions which will require our notice, is a work which appeared early in the seventeenth century, in many respects peculiar in its style and in the opinions which the author adopts, but of real value, as possessing the merit of pointing out a precise mode of ascertaining with accuracy the rate of the pulse, by means of an instrument adapted for measuring short intervals of time. This was done by Sir J. Floyer, in "The Physican's Pulse Watch," published in 1707. The instrument which he describes is indeed awkward in its construction, and must have been inconvenient in practice, but it deserves to be recorded, as being the first step of an important improvement.

In the year 1731 a singular work made its appearance, written by Solano, a native of Lucca, but who passed the greatest part of his life in Spain; it was entitled "Lapis Lydius Apollinis."

In the course of his practice he had met with some cases of what is termed the rebounding pulse, and being struck with its peculiarity, and with the symptoms which succeeded it, he was led to pay particular attention to the various states of the pulse, and to the morbid changes which appeared to be connected with them. He accordingly directed his attention almost exclusively to this function, and he is said to have arrived at an inconceivable degree of acuteness in predicting the event of disease by the peculiar indications of the pulse. The result of his experience, real or supposed, forms the subject of his volume, which obtained, at the time of its publication, a considerable degree of celebrity.

The investigation was zealously pursued by Nihell, an English physician, who likewise resided in Spain, and who undertook to give to the world the principles of Solano under a more intelligible form, and divested of a degree of obscurity which is attached to the original. Accordingly, in the year 1745 Nihell published his "New and extraordinary Observations concerning the Predictions of Crisis by the Pulse."

A few years after the appearance of Nihell's treatise, a work of a similar kind was published in France by Fouquet; who, proceeding upon the plan of Solano, endeavoured to point out the connection between certain peculiar states of the pulse and the affection of peculiar organs of the body.

The subject was still farther prosecuted by a learned countryman of Fouquet's, Bordeau, who, in the year 1756, published his "Recherches sur le pouls par rapport aux crises." In this treatise he proceeds upon the method of Solano; but he goes even beyond him in the minuteness of his distinctions, and the apparent accuracy of his discriminations; and from these he professes to draw a system of indications and prognoses, which, although in some of its parts it may not be altogether without foundation, is generally admitted to be derived from subtile and over-refined distinctions, which it is impossible to recognise, and which, for the most part, can have no real existence. It does not appear that in this country the system of Solano ever had any considerable number of adherents, while in France the learning and ability exhibited in the work of Bordeu, aided also by his reputation as an able and successful practitioner, contributed to give a degree of weight and authority to his opinions, greater than was due to their intrinsic merit. Even in the present day, we observe in the French school an attempt at nice discriminations of the pulse, which are conceived by the English to be altogether imaginary, a state of things which may probably be traced, in some degree, to the writings of Bordeu.

For the opinions which have been, of late years, generally embraced in this country respecting the pulse, we are probably indebted in no inconsiderable degree to two short, but very valuable treatises; the first consisting of an essay, which was read by Dr. Heberden before the College of Physicians in the year 1768; the latter, of the "Observations respecting the Pulse," by Dr. Falconer, published in the year 1796.

Dr. Heberden has the merit of having freed the subject from most of the subtile and over-refined distinctions which had been introduced into it, in the first instance by the followers of Galen, and afterwards by those who adopted the opinions of Solano. He informs us that his object was to direct the attention of the practitioner to "such circumstances of the pulse, in which they could neither mistake nor be misunderstood." He continues: "what I mean is, the quickness or frequency of the pulse, which, although distinguished by some writers, I shall use as synonymous terms." Proceeding upon this principle, he gives us the valuable results of his own observation on the respective frequency of the pulse at different ages and in different states of the constitution, and points out various circumstances in which the frequency of the pulse, considered by itself, without reference to other symptoms, was found to be a very inadequate criterion of the nature and degree of disease.

Nearly a similar view of the subject was taken by Dr. Falconer. Referring to the essay of Dr. Heberden, he has the following remark. "It has been reserved for the good sense and clear understanding of a physician, who does honour to our own country, to free the study of the profession from many needless incumbrances of this kind, and to direct the attention of practitioners to the only circumstance respecting the pulse which is capable of communicating accurate and distinct ideas, or of affording decisive indications." He further agrees with Dr. Heberden, that the quickness and frequency of the pulse are to be regarded as synonymous terms, and characterizes the frequency "as the only circumstance respecting it (the pulse) of which we can form any clear or determinate idea, and which we can be assured conveys the same information to others that it does to ourselves;" while he speaks of the other distinctions as fanciful or whimsical, and as serving to perplex and embarrass the practitioner.

With the greatest respect, however, for these individuals, who may be justly regarded as among the most enlightened and candid physicians of modern times, we conceive that they have attempted to simplify the subject too far, and that, in discarding a mass of erroneous notions, they have fallen into the opposite extreme. But whatever we may think of their opinions on this point, the facts and observations which they have adduced are of the highest importance, and rest upon authority which can never be called in question.

It will be scarcely necessary to pursue the historical part of this article below the termination of the last century, for although we have many very valuable observations on the pulse of a later date, they are either contained in works principally devoted to other topics, such as general histories of medical science, and accounts of particular diseases and individual cases, or they are written for the express purpose of establishing and elucidating some physiological position, which will be more conveniently discussed in the second part of this article.*

* For a more minute account of the opinions respecting the pulse, we may refer especially to the histories of Le Clerc and Sprengel, and to Haller, El. Phys. lib. 6, sect. 2; also to the art. *Pouls*, in the Dict. des Scien. Méd.

II. **Physiology of the Pulse.** — In treating of the physiology of the pulse there are various points that present themselves for our consideration. In the first place we must inquire into the cause of the pulse, and when we have ascertained the cause, we shall be prepared to investigate the exact nature of the effect, and what relation it bears to the other functions of the animal economy.

Since the immortal discovery of Harvey, it is universally admitted that the pulse depends immediately upon the action of the heart, which, by its contraction, expels a portion of blood from its cavities into the great arteries. The contraction, or, as it has been termed, the systole of the heart, must therefore correspond, in point of time, with the stroke of the artery, while, during the diastole of the heart, the artery returns to its quiescent state. But although there can be no difference of opinion on this point, there are various subordinate questions, which have been the subject of warm and protracted discussions, some of which remain still undecided.

Of these, one of the most important is, whether the arteries themselves possess any contractile power, by which they are enabled to co-operate with the heart. The contractile power of the arteries has been supported by direct experiments, and especially by those in which the blood was found to be propelled along the vessels after the heart was removed from the body; while, on the contrary, this property has been denied by other physiologists, because, in experiments made for the express purpose, the artery could not be made to contract by the application of those agents which are known in ordinary cases to stimulate the muscular fibre. There is certainly some difficulty in reconciling the apparently discordant results; but, upon the whole, the weight of evidence is in favour of the contractile power of the arteries; for it appears almost impossible to explain various phenomena without admitting this power, while the negative results that have been adduced against this opinion are explicable upon other principles. We may therefore assume it as an established point, that the blood is propelled along the vessels by the joint power of the heart and arteries.

Proceeding, however, upon this position, that when the heart contracts, a certain impulse is propagated through the artery which causes it to strike the finger, it still remains to be ascertained what is the exact nature of this impulse. We may inquire whether the vessel be actually distended, so as to have its diameter increased, or is it merely extended in length, or displaced? or without having its size actually augmented, or being removed from its situation, is it only rendered more tense or firm, or what other change does it experience? When we estimate the bulk of the blood sent into the aorta at each contraction of the heart, and compare this with the quantity of blood previously contained in the vessels, although we might theoretically suppose that the diameter of any particular artery was actually increased, it must be admitted that the increase of bulk would be much too small to be perceived by the finger, or to produce the sensation which is conveyed to us by the pulse. Hence we may conclude that the terms systole and diastole are scarcely applicable to the different states of the artery; for although we may conceive them to be technically correct, when considered as a question of theory, we cannot admit of their actual existence in any sensible or perceptible degree.

As to the extension or displacement of the artery, it appears certain that when the jet of blood is forcibly projected into a flexible tube, like that of which the artery is composed, there will be an effort produced to straighten it and to diminish its flexures, and at the same time to extend it in a longitudinal direction, as far as the texture of the organ itself and its connection with the neighbouring parts will permit. There is, however, reason to believe that these changes, although they may actually take place to a certain extent, do not exist in sufficient degree to produce all the effect which is experienced, and we are therefore induced to search for some other cause of the phenomena.

The solution of the problem was attempted by Dr. Parry,* who, after proving the insufficiency of all the former modes of explanation, proposed a new view of the subject. We shall quote the words of the author, as they express, in a short compass, the fundamental positions on which the hypothesis rests. "In the larger arteries there is no sensible dilatation or contraction,—therefore the pulse cannot depend on this alternation.—The chief cause of the pulse is a strong and predominant impulse of distension from the systole of the left ventricle, given by the blood as it passes through any portion of an artery forcibly contracted within its natural dimensions." The pulse is felt when the motion of the blood is impeded by the compression of the artery, and it is the resistance to this obstruction which produces the pulse. We feel much disposed to acquiesce in Dr. Parry's opinion, at least it may be asserted that there is no other which gives a sufficient explanation of the phenomena, while at the same time there is nothing in the hypothesis either repugnant to the laws of the constitution, or inconsistent with the structure and properties of the organs in question.

It will follow as a consequence of this opinion, that the pulse must be progressive, i. e. the impulse must be made on the different parts of the artery at different times, corresponding to their distance from the heart. But although this may be theoretically true, it has been questioned whether the difference be really perceptible, and many very accurate observers have not hesitated to affirm that they have been unable to recognise it. There are, however, physiologists of the first eminence, who inform us that they can perceive a difference in point of time in the beat of the different parts of the arterial system. Considering, therefore, that a positive fact, where the authorities are equal, is to be preferred to a negative one, we must admit that the progressive beat of the arteries is perceptible.

Another question which, like the last, must be answered partly from theory, and partly from observation, is whether the force of the different parts of the arterial system always maintains the

* Experimental Inquiry concerning the Arterial Pulse, 1816; with additional experiments by his Son, 1819.

same relation to that of all the other parts, and to the action of the heart. If the action of the heart be increased in a certain ratio, is that of every artery increased in the same ratio, or is the same ratio observed in every increase or diminution of action which may occur in any part of the arterial system? If the heart were the sole impelling power, this equality of ratio must necessarily be preserved; but if the arteries themselves partake of this action, and co-operate with the heart in the propelling power, it will follow that a local cause may produce a local effect; and this we in fact find to be the case.

If we suppose that the arterial system derives its power ultimately from the force of muscular contractility, and that this is exercised conjointly by the heart and the arteries, we may inquire to what change of properties or of constitution are the parts concerned in this operation obnoxious, which may produce an actual or perceptible effect on the pulse; and further, what is the nature of the changes which would be thus produced.

The mechanical structure of the parts we may conceive to remain unchanged, but the force of contractility is perpetually varying. And although we may suppose that the heart and arteries are not under the direct influence of the nervous power, yet we are disposed to acquiesce in the doctrine of those physiologists who maintain that they are indirectly affected by it, in the same manner with the involuntary muscles generally, so that we have here another source of variation in the pulse.

The function of respiration exercises a most important influence over the circulation. The essential object of this function is to produce such a chemical change in the blood as to enable it to maintain the contractility of the muscular parts, and among others, that of the heart itself. Any interruption to this change in the nature and constitution of the blood will necessarily impede the action of the heart, independently of any direct change in its susceptibility, while a still more material change in the circulation will be produced, if both the nature of the blood and the power of the heart be simultaneously affected. The function of assimilation is still more immediately connected with the process of sanguification, and consequently with the quantity and quality of the blood, so that we have here two direct and immediate causes always in operation, which, either separately or conjointly, may contribute to affect the state of the pulse. From these considerations it will appear that, independent of any external agency, we shall have a sufficient number of changes in the powers or actions connected with the circulation, to account for all the actual varieties that are observable in the state of the pulse, and to serve us as a basis on which to construct a theory of the cause and nature of these variations.

Let us now attempt to apply these observations to explain the phenomena of the pulse. We may arrange all its varieties under the three relations of time, force, and equality, considered either simply or in combination. Thus the strokes of the artery may be in the simple relation of frequent or rare, strong or weak, regular or irregular, or we may have the combined relations of frequent and strong, weak and regular, &c. It will be a question, however, for consideration, whether all the varieties that can be actually detected are reducible to these three simple or combined relations; and in order to elucidate this point, it will be necessary to determine what are the characters of the pulse which can be clearly recognised, and are generally allowed to exist.

The first is that which depends upon the simple relation of time, constituting the frequent or rare pulse, indicating merely the number of strokes in a given period. The next variety is the quick or the slow pulse, including something beyond the mere number of beats in a given time, and taking into account the period occupied by each individual pulsation. From what has been stated in the first part of this article, it will appear that it has been questioned by physiologists and physicians, whether it is possible to distinguish between these two states of the pulse, or rather, indeed, whether this difference actually exists; whether, for example, a pulse can be at the same time both rare and quick, or frequent and slow. This point formed the subject of a very warm discussion between the celebrated rivals Stahl and Hoffmann, about the beginning of the last century, the former maintaining the affirmative, and the latter the negative opinion. We have seen above, that the high authority of Heberden and Falconer is in favour of the opinion of Hoffmann, yet we have also high authorities on the other side of the question; and proceeding upon the same principle as on a former occasion, we do not hesitate to decide in the affirmative. It may indeed be impossible to discriminate between a quick and a frequent pulse where the frequency is considerable; yet in cases of less frequency, we conceive that a difference may be detected. These are the only simple relations of time.

With respect to the second class of relations, that of force, we have first the most simple character of strong and weak, depending directly upon the degree of force with which the heart propels the blood into the arteries. It may be doubted whether there be any state of the constitution in which the contractility of the heart is increased or diminished, without the action of the arterial system, taken in its whole extent, being likewise increased or diminished; nor, if this condition should exist, are we in possession of any method of detecting it through the medium of the pulse.

We may conceive a state, in which the contractility of the heart may remain unchanged, but in which the nervous energy may be increased or diminished, in which case an indirect effect may be produced on the pulse, giving rise to two possible variations, the one depending on an increase, the other on a diminution of nervous power. Then again, conceiving the muscular and the nervous powers to be derived from different sources, and not necessarily dependent on each other, we have the farther possible modifications of increased contractility, while the sensibility is either increased or diminished, and the reverse. But although some of these may be regarded as possible and even not unfrequent occurrences, it does not appear that we have any means of recognising their effects on the pulse, or of distinguishing them from each other. The only characters

of the pulse which belong to the relation of strength, besides that of the simply strong and weak pulse, is the hard or soft, and what is perhaps nearly the same, or differing from it by a minute shade only, the quality which has been termed tension, where, without the actual bulk of the artery, or the force of the heart being increased, a sensation is communicated to the finger of great firmness or density. It is probable that under one or other of these characters may be comprehended all the essential variations of the pulse which are connected with the simple relation of force.

[Most of the theories of the pulse take the contractility of the artery too little into account. In pathology, where we have an opportunity for observing the pulse in various phases, we have sensations communicated to the finger which it is difficult to explain upon any theory, except that of the compound action of heart and arteries. The arterial system is manifestly more or less affected by the nerves distributed to it: it may be stimulated by irritants applied to the great nervous centres, or to the nerves passing to it; and this is, doubtless, the cause of many of the modifications of arterial tension which we notice in disease. No inflammation can affect a part of the system, for any length of time, without both heart and arteries participating, and affording unequivocal signs of such inflammation.]

We must next speak of those variations of the pulse which proceed upon the relation of equality. These naturally arrange themselves under the two heads of equality as to time, and equality as to force. The first constitutes the regular or the irregular pulse, and the irregularity may be of two kinds; when one beat among a certain number of strokes is omitted, as in the intermitting pulse, or when the beats generally bear no uniform relation to each other. With respect also to the irregularity of force, we have, in like manner, two varieties; the first, where there is a general inequality in the strength of the pulsations compared with each other; the second, that state of the pulse where a weaker and a stronger beat succeed each other, with at least a certain degree of uniformity. One variety of this has been termed the rebounding pulse, and there are others, much insisted upon by the older writers, and perhaps not altogether without an actual existence, where this change of force is continued through two or three strokes, constituting a kind of increasing or decreasing series, to which the terms *inciduus* and *miurus* (μείουρος) have been respectively applied.

If we now bear in mind the three general causes which we have supposed to affect the circulation, the vital powers of contractility and sensibility, and the state of the circulating fluid, we shall perceive that the relations of time, force, and equality may be, each of them, supposed capable of being influenced by the third of these causes, which will give rise to an additional set of combinations, of possible, perhaps some of them of frequent occurrence. Thus, what is termed the full or small pulse probably depends upon an excessive or a deficient quantity of blood in the vessels. That peculiar state of the pulse in which the sensation conveyed by the artery to the finger has been likened to that of a thread, a wire, or a cord, may be supposed to depend upon the small quantity of blood in the vessel, combined with an increased or diminished contractility of the heart, while the contrary state of a sluggish or an oppressed pulse, and the like, may be attributed to an unusual fulness of the vessels, the vital powers of contractility and sensibility not being increased, or even one or both of them being diminished.

The varieties in the pulse which have been enumerated above, are supposed to be derived from, or to be dependent on, the general or ordinary actions of the animal economy, and to be explicable by a reference to the principles which influence these actions. There are, however, many other variations which profess to be the result of observation and experience, but which are admitted to be altogether empirical, and of which no explanation is attempted to be given. Some of these were referred to in the first part of this article. Such are, for the most part, the different states of the pulse pointed out by Solano and his followers, and especially by Fouquet and Bordeu. The greatest part of these we may unhesitatingly pronounce to be altogether without foundation; there are, however, some of them which are supported by such numerous and learned authorities that it would be improper to pass them by without noticing them a little more particularly.

It has been a favourite notion with many physiologists, ancient as well as modern, that diseases of the different regions of the body, for example, of the upper, the middle, and the lower, might be recognised by corresponding differences in the state of the pulse. But we may venture to assert that this doctrine is erroneous. The mere local situation of a disease can have no effect on the pulse, except as far as regards the distance of the organ from the centre of the circulation; while, on the contrary, wherever the morbid part be situated, it is easy to imagine that the function to which it is subservient, or even its texture and composition, may materially affect the condition of the circulation, and that this may possibly be detected by the state of the pulse. Antecedently to all experience on the subject, we might expect that an inflammation of any part connected with the brain or an organ of sense would produce a different effect upon the pulse from an inflammation of the lungs, and this again from a similar affection of the stomach or the intestines. We may farther conceive that an inflammation of a mucous, a serous, a muscular, or a membranous texture, would respectively impress a specific character on the circulation, as manifested by the pulse; but this will be altogether independent of the mere locality of the organ, and must be referred to a totally different principle. The idea which was long prevalent of there being a connection between the diseases of each side of the body and the pulse of the same side, would appear, in like manner, to be entirely without foundation.

There is, however, another set of causes which materially affect the pulse; these may be divided into internal and external. The internal are connected with the original powers or constitution of the body, or with its natural and ordinary progressive changes. Such are age, sex, temperament, and peculiar idiosyncracies, the states of sleep and watching, of repletion and inanition,

mental emotions of all kinds, and the revolution of the diurnal period. All the above are within the limits of health, and the catalogue is to be augmented by the long and melancholy train of morbid affections. Among the external causes are climate, temperature, various atmospherical changes, peculiarities of dict, modes of life, certain occupations and acquired habits. All these circumstances more or less affect the pulse, and cause it to deviate from what may be regardcd as its medium or standard condition, and they are all of them objects of especial attention to the judicious and intelligent physician. The further consideration of these may, however, be more conveniently referred to the third division of this article.

III. **Pathology of the Pulse.**—After having made ourselves acquainted with the physiology of the pulse, we shall be prepared for entering into the consideration of its pathology, and for inquiring into the degree in which it may serve us as an indication of the nature and seat of disease.

We have had ample occasion to remark upon the great difference of opinion that has existed on this latter point among the most eminent men both in ancient and modern times. While Hippocrates and Celsus paid but little attention to the indications of the pulse, Galen, on the contrary, fell into the opposite error, and aimed at what was considered, even by some of his contemporaries, as an excessive and over-refined minuteness. Among the moderns, the prevailing disposition has been to regard the pulse as one of the most important means of ascertaining the nature and progress of disease; and it may be asserted generally, that the pulse is among the first objects to which the practitioner directs his attention. Yet even among the most enlightened and candid of the moderns, we have opinions promulgated which must diminish the confidence we might otherwise be disposed to feel on this subject. We have seen above, that Dr. Heberden limits the characters of the pulse, which are available by the practitioner, almost to its different degrees of frequency; and with respect to its indications generally, the tendency of his observations is to show that the pulse is, in many cases, a very inadequate guide in enabling us to form our indications, and that not unfrequently it would lead us to absolutely erroneous conclusions.

In this state of uncertainty it may be useful to recur to first principles, and to endeavour to unite theory with experience and observation. If there be a state of the system in which the muscular contractility and the nervous energy are one or both of them increased, we might expect that an increased action of the heart would be the consequence, and that this increased action would be communicated to the arteries, and would, according to circumstances, produce a full, a hard, a frequent, or a quick pulse, or any combination of these conditions. If, on the contrary, the force of the heart be diminished, either directly by the diminution of its contractility, or indirectly by that of the nervous influence, the blood will be propelled with less force into the arteries, and will be moved with less facility along them. The pulse will then become languid or oppressed, feeble, small, intermitting, or irregular, according to the quantity of blood in the vessels, and the relation of this to the vital powers.

Proceeding, then, upon the united basis of theory and observation, it may be useful to consider, first, what characters of the pulse are the most distinctly perceived and clearly discriminated; and, secondly, to inquire what conditions of the vital powers or of the functions may be supposed capable of producing a distinct and specific change in the state of the pulse.

But before we proceed to examine into the relation which these various states of the pulse bear to the different morbid conditions of the body, it will be proper to offer a few brief remarks on the effect of the circumstances alluded to above, which, independently of disease, are supposed, in a greater or less degree, to influence the circulation.

The first in point both of order and of importance is the age of the subject. The pulse of a newly-born infant is 130 or 140 in a minute, nearly twice as frequent as that of an adult; but its frequency soon begins to diminish, its mean rate during the first month being about 120. During the first year it falls to about 110; during the second year to about 100; from the third to the sixth year it may be estimated at about 90; and by the tenth or twelfth year it arrives at the state in which it remains for the greatest part of life.

[More accurate observations have indicated conditions of the pulse in the different ages that had been overlooked. In infancy, it is generally irregular and always rapid; and in old age, contrary to the views generally embraced, it often certainly becomes more rapid than in the adult. Researches by MM. Hourmann and Dechambre (*Archiv. général. de Médecine*, 1835) on 255 women, between the ages of 60 and 96, have shown the average number of the pulse to be 82-29. M. Rochoux, however, (art *Pouls*, in *Dict. de Méd.* 2d édit. xxv. 614, Paris, 1842; see also Piorry, *Traité de Diagnostic*, § 555,) still considers that, as a general rule, the pulse diminishes in frequency in the progress of age; and the same inference has been drawn, it will be seen, by Dr. Knox. It is important, also, to remark, that Dr. Gorham (*Lond. Med. Gaz.* Nov. 25, 1837,) found the mean number of the pulse, from five months to two years old, to be 130; and 107.63 from two to four years old; from which time until the 10th year, the number continues almost the same. Unless these facts be borne in mind, that velocity of the circulation, which is healthy, may be regarded as morbid. (See, on this subject, Trousseau, in *Journ. des Connaiss. Méd. Chir.* Juillet and Août, 1841, or *Amer. Journ. of the Med. Sciences*, Oct. 1841, p. 458, and Jan. 1842, p. 199.)]

Numerous observations have been made for the purpose of fixing the average rate of the pulse in the healthy adult. This subject was particularly attended to by Dr. Falconer, and we find in his essay a copious collection of observations made by himself and others, in order to ascertain this point; the number which he fixes upon is 75, and there appears sufficient ground for acquiescing in his conclusion. It is further to be remarked that the pulse is more irritable in youth than in more advanced age, being more affected both by external and internal causes.

With respect to the two sexes, it is generally

admitted that the pulse of the female is more frequent than that of the male, perhaps eight or ten beats in the minute; it likewise resembles the pulse of youth in its liability to be affected by all those circumstances which influence the state of the circulation. An analogous observation may be made with respect to temperaments; in the sanguine temperament, where the constitution more resembles the state of youth and of the female, the pulse is more frequent and more irritable than in that of an opposite character. With respect to idiosyncrasies, it is obvious that no general remarks can be made; but it is important for the practitioner to be aware that individuals, who may resemble each other in all that respects age, sex, or temperament, may still have a different rate of the pulse, and this independent of any apparent morbid condition or assignable cause.

[In some individuals in health, the number of beats is singularly few. The pulse of a healthy adult, known to the author, was, on the average, 36 per minute. Not unfrequently, on the other hand, it exceeds 100 in health. Strange to say, the pulse has been known to be wholly absent, without the health being interfered with. Such a case has been related by Professor Jackson, of Philadelphia, (*Principles of Medicine*, &c. p. 492, Philad. 1832); and for other cases, see the writer's *Human Physiology*, ii. 164.)]

The states of sleep and watching, and more generally of rest and motion, very considerably affect the pulse. The observations that have been made on the pulse during sleep are not altogether uniform, but they tend generally to the conclusion, that the pulse becomes slower during this state. With respect to the effect of motion, every one is aware how much the pulse is increased in frequency by exercise of any kind; the degree of this increase being partly in proportion to the degree of exercise employed, and partly to the previous state of the constitution or the ordinary habits of the individual. On this subject, as well as on many other points connected with the mechanism of the pulse, we have a number of valuable observations by Bryan Robinson, a writer whose facts appear to be correct and worthy of our attention, although his physiological hypotheses are, for the most part, discarded. (Treatise on the Animal Economy, 1732.)

[Dr. Guy (*Guy's Hospital Reports*, April, 1838, p. 92. See, also, Dr. John M. B. Harden, in *Amer. Journ. of the Med. Sciences*, for April, 1843, p. 340), from numerous observations, found the pulse in healthy males, of the mean age of 27 years, in a state of rest, 79 when standing, 70 sitting, and 67 lying; the difference between standing and sitting being 9 beats; between sitting and lying, 3 beats; and between standing and lying, 12 beats. When all exceptions to the general rule were excluded, the numbers were,—standing 81; sitting 71; and lying 66,—the difference between standing and sitting being 10 beats; between sitting and lying 5 beats; and between standing and lying 15 beats. The effect produced upon the pulse by change of posture, Dr. Guy ascribes to muscular contraction, whether employed to change the position of the body or to maintain it in the same position. In children the difference between the pulse in the sitting and lying posture is often very marked. In a boy, six years of age, the writer found it to amount to fifteen beats; and Dr. Evanson (*Treatise on Diseases of Children*, by Drs. Evanson and Maunsell, Amer. edit. by Dr. Condie, p. 19, Philad. 1843) states, that he has often found the pulse,—which at night, during sleep, was 80, full and steady—up to 100 or even 120 during the day, small and hurried, and this in children six or seven years of age, and in perfect health.]

The state of the system with respect to repletion or inanition very materially affects the pulse. The taking of food increases both its frequency and its fulness, and that often in a very considerable degree. After a meal which cannot be regarded as excessive or intemperate, the pulse may be increased by one-fifth of its average number of beats, while its strength and fulness are almost equally augmented. When abstinence is carried to a great and unnatural excess, the pulse, although much diminished in strength, appears to be increased in frequency; but this occurrence can seldom be observed without the presence of some other disease, which is the immediate cause of the abstinence, and which would probably of itself affect the pulse.

Every one is aware how much the circulation is affected by mental emotions of all kinds. If we arrange them, according to the ordinary distribution, under the two great classes of exciting and depressing, we shall find that they, each of them, increase the frequency of the pulse; the former, however, for the most part, have the effect of also increasing its force, while the latter, on the contrary, render it more feeble.

It is generally admitted that the pulse undergoes a kind of periodical revolution during the course of the day, and this independent of any of those circumstances, external or internal, which might be supposed to affect it. This subject has been attended to by various physiologists, and among others by Bryan Robinson and Falconer, who have given us tables of the results of their observations. We are, however, scarcely able to draw any conclusions from them, except that the pulse is less frequent in the morning, and that it has a general disposition to become more frequent as the day advances; but it appears very difficult, if not impossible, to determine in what degree this increased quickness is to be attributed to food, exercise, or to other exciting causes.

[From observations made by Dr. Knox (*Edinb. Med. and Surg. Journ.* April, 1837), he has drawn the following deductions on this subject, which accord greatly with those of Dr. Guy on the same subject (*Ibid.* Jan. 1841, p. 90): 1. The velocity of the heart's action is in a direct ratio with the age of the individual,—being quickest in young persons, slowest in the aged. There may be exceptions to this, but they do not affect the general law. 2. There are no data to determine the question of an average pulse for all ages. 3. There is a morning acceleration, and an evening retardation in the number of the pulsations of the heart, independently of any stimulation by food, &c. 4. The excitability of the heart undergoes a daily revolution; that is, food and exercise affect the heart's action most

in the morning, and during the forenoon, least in the afternoon, and least of all in the evening. Hence it must be inferred, that the pernicious use of spirituous liquors must be greatly aggravated in those who drink before dinner. 5. Sleep does not farther effect the heart's action than by a cessation of all voluntary motion, and by a recumbent position. 6. In weak persons, muscular action excites the action of the heart more powerfully than in strong and healthy individuals; but this does not apply to other stimulants, to wine for example, or to spirituous liquors. 7. The effects of the position of the body, in increasing or diminishing the number of pulsations, is solely attributable to the muscular exertion required to maintain the body in the sitting or erect attitude: the debility may be measured by altering the position of the person from a recumbent to a sitting, or to the erect position. 8. The most powerful stimulant to the heart's action is muscular exertion. The febrile pulse never equals this.]

We are still less able to draw any general conclusions respecting the operation of the external causes, which were enumerated above as liable to affect the pulse; it is less easy to observe their distinct and separate action on the system, and it may be apprehended that the operation itself is in most cases less uniform. If there be any exception, it is with respect to external temperature, which seems very generally to increase the frequency, and in most cases the strength and fulness of the pulse. Temperature, however, like all other stimulating agents, if carried beyond certain limits, either as to quantity or duration, exhausts the vital powers, and produces a state of weakness, which may be recognised by the pulse. Excessive cold exercises a directly debilitating power over the system, and produces a corresponding effect on the pulse. There is, however, a considerable diversity in the accounts which we have on this subject, in consequence of the difficulty there is in ascertaining the point at which cold may be considered as exceeding the limits of the salutary action which it exerts when in a moderate degree only. With respect to the other external causes which affect the pulse, we may remark that they are all of them points to which the practitioner should direct his attention, in order that he may learn to distinguish between the effects which proceed from these causes, and those which belong to the diseases under treatment.

To return from this digression to consider the characters of the pulse, the following may be enumerated among those which are the most distinct and unequivocal. In the relations of time, the pulse may be frequent or rare, quick or slow; in the relations of force, it may be strong or weak, hard or soft, full or small, free or compressed: in the third relation, of equality, we have the irregular pulse with respect both to time and force, with the varieties of each, the intermitting, the rebounding, the fluctuating or wavering pulse, &c.

In considering the changes that may be communicated to the pulse by a change in the action of the heart, we may remark that, of the two vital powers which contribute to this action, the nervous power is the one the most liable to variations, and the most under the influence of external agents; we therefore assume that, in most cases of increased or diminished action, the change originates in an affection of the nervous system. It hence becomes necessary to consider what are the laws which regulate the actions of the nervous system—at least what are the changes in this action which are especially applicable to the case in question. Now there are two states of the nervous system recognised by physiologists, which must influence the action of the heart in such a way as to affect the frequency of the pulse; the first condition, which has been termed the increased mobility or excitability of the nervous system, the other a sedative operation, tending directly to diminish its action. The effect of the increased mobility of the nervous system is to render a part under the influence of the nerves more susceptible of action, while the force of the action is not proportionably increased; the operation of a directly sedative agency is to diminish the action of the parts in all respects, both as to susceptibility and to force. The diseases of hysteria and apoplexy, or rather the tendency to these diseases, may be cited as affording us, respectively, types of these two states of the nervous system; the former giving rise to frequent and irregular contractions of the muscles, the latter tending altogether to destroy their contractility. Hence we observe a foundation for what at first view might appear a contradiction, that a debilitating cause, acting on the heart, may in one case cause an increased, and at another time a diminished frequency of the pulse.

It is generally admitted by physiologists, that a principle analogous to what has been described as occurring in the nervous system exists also in the muscular; that absolute force and susceptibility of action bear no necessary relation to each other, but that each of them may be increased or diminished without a corresponding change in the condition of the other. With respect to the pulse, however, it is admitted that we are, for the most part, unable to distinguish between the affections of the muscular and the nervous systems; consequently all that we can aim at is to ascertain in what manner or in what degree the morbid cause acts generally upon the powers which increase or diminish the susceptibility or force of the contractions of the heart.

It will be scarcely necessary to offer any remarks on the mode of feeling the pulse. We have, indeed, in some of the older writers, many minute directions on this subject, and in some French works, even of recent date, the "exploration" of the pulse is treated of in detail, as an elaborate art of difficult attainment. It no doubt requires accurate observation and minute attention to appreciate all the changes to which the pulse is liable, but there appears to be nothing in the subject of peculiar difficulty, or which will not be overcome by a due familiarity with the phenomena of disease. The anatomical structure of the part, and its practical convenience, render the artery at the wrist, in a great majority of cases, the most eligible part for ascertaining the state of the pulse; we may occasionally find it necessary to examine the artery in the neighbourhood of a part which is supposed to be the immediate seat of the disease, and in some instances we compare the action of

different arteries with each other; but these are points which scarcely require or admit of general directions.

What has been stated above bears immediately upon the second point which we proposed for consideration, viz. to inquire what condition of the vital powers or of the functions may be supposed capable of producing a distinct and specific effect upon the pulse, and what are the diseases which derive their distinctive characters from the changes consequent on these conditions. Now we shall find that the diseases in which the action of the heart is more immediately or directly concerned are those which we referred to the great class of febrile affections. These may be arranged under the two divisions of fevers that originate in, or are essentially connected with, increased action of the vital powers, and those which originate in a diminished action of these powers; the first constituting what is popularly termed inflammatory fever, the synocha or cauma of systematic writers; the latter the low or nervous fever, the typhus of the nosologists. If to these we add a third class of diseases, which depend upon a directly sedative operation on the nervous system, nearly corresponding to the anæsthesiæ of the nosologists, we shall have three great divisions, to which we may refer all the various changes in the state and condition of the pulse which can be easily reduced to any general principles.

We are now arrived at that part of the subject to which all the rest ought to be subservient, and which alone gives it its value—the practical application of our theoretical principles; yet, important as it is, on this occasion it must necessarily be passed over with a very slight notice. All that can be accomplished in an essay like the present, is to establish and illustrate certain general positions, which may be applicable to each particular disease, or even to each individual case,—a detail which would be inconsistent with the nature and the limits of our article, but which will be amply supplied by the other parts of this work.

The object of the practitioner is to ascertain, if possible, in the first instance, what is the ordinary state of the pulse of each individual, as depending upon his peculiar constitution or habits; and, secondly, how it may be supposed to be affected by the circumstances, either external or internal, which were enumerated above, and which are independent of the disease in question. In the third place, he must ascertain the state of the pulse with respect to its three principal relations of time, force, and equality, considered either simply or in combination, and endeavour to trace their connection with the supposed cause of the disease, and with the derangement which has been induced in the various powers and functions of the system. These he will probably find it convenient to refer to one or other of the three great classes mentioned above, and he must regulate his practice, and form his diagnosis and prognosis by still farther viewing them in connection with the other symptoms of the disease. The result of this process will be, that by referring to the physiological principles which we have attempted to establish, the practitioner will frequently be enabled to explain what would otherwise be obscure and unintelligible; yet it must be acknowledged, on the other hand, that he will meet with numerous anomalies which he will find it impossible to reduce to his system, and which can only be duly appreciated by a careful and diligent observation of the phenomena of disease, and by steadily preferring the result of experience to the deductions of any theory, however plausibly formed or ingeniously supported. [See on the whole subject of the pulse, Piorry, *Traité de Diagnostic*, § 537.]

John Bostock.

PURGATIVES.—See Cathartics.

PURPURA.—The terms *purpura*, [or *porphyra*] *purpura hæmorrhagica*, and *hæmorrhœa petechialis*, are employed to denote that affection which was formerly distinguished in medical writings by the designations of morbus maculosus hæmorrhagicus, petechiæ sine febre, phœnigmus petechialis, (*Sauv.*) &c. This disease is characterized by an efflorescence on the skin, occurring independently of primary fever, consisting of red, purple, or livid spots of various sizes, (termed petechiæ, vibices, and ecchymoses,) and in its more severe form accompanied by hemorrhage from various parts of the body, chiefly from the mucous membranes. The spots are seldom elevated above the level of the surrounding cuticle; they are unattended by itching or any uneasy sensation; and on division of the cuticle by a scalpel they are found to consist of minute effusions of blood. They are therefore essentially different from every form of rash or other cutaneous eruption; and are properly considered as the result of a *cutaneous hemorrhage*.

[In consequence of the appearance of the skin, purpura has been commonly classed amongst cutaneous diseases. Willan has treated, under the head of purpura, of the land-scurvy, and of the petechial spots of malignant fever,—*petechia contagiosa;* yet he has omitted sea-scurvy,—an affection almost identical with land-scurvy. They are all—as a general rule—dependent upon a similar depraved condition of the fluids and solids; are true cachexies, in other words; and have accordingly been treated of, by the writer, under Scorbutic Cachexia. (*Practice of Medicine*, 2d edit. ii. 632, Philad. 1844.)]

Petechiæ (a name introduced into nosological language from the Italian *petecchia*, and supposed to be originally derived from their resemblance to flea-bites) have been long noted as a symptom in continued fevers and other febrile diseases, in which they have been supposed to indicate peculiar malignancy. (See the article Fever.) From their constant occurrence in certain epidemic fevers, these were considered as constituting a specific exanthematous disease, which was described in nosological systems and practical writings under the names of petechiæ, febris petechialis, febris purpurata, &c. The occurrence of petechiæ in continued fever, no less than in small-pox, measles, &c. is now universally allowed to be a contingent symptom, and most commonly arises from the influence of foul air, a hot regimen, the neglect of purgatives, or similar errors in treatment. It is accordingly much less frequent than formerly. *Petechial fever* is the "purpura" of Sauvages' nosology; a term which had previously been used

in the same sense by Riverius, Diemerbroeck, &c. By others of the old writers it had been employed to signify affections totally different, viz. various forms of papulous eruptions and rashes, as red-gum, lichen, miliaria, nettle-rash, measles, and scarlatina. (Willan on Cutaneous Diseases, p. 452.—Bateman, Synopsis, p. 103, third edit.) We must therefore take eare not to apply their observations to what is now termed purpura.

We owe the name of purpura in its present acceptation to Dr. Willan. In his nomenclature of cutaneous affections it is used as a generic term, to include every form of petechial eruption, febrile or non-febrile. He therefore includes under it, as a species, purpura *contagiosa*, the petechial eruption in continued fevers; a name every way objectionable, as it would tend to perpetuate the ancient errors of the idiopathic nature and specific contagion of those petechiæ. Under the names of *P. simplex*, *P. hæmorrhagica*, and *P. urticans*, he describes "three striking varieties" of petechial eruption independent of primary fever,—varieties which confessedly differ chiefly in degree, and which, under the general name of purpura, form the subject of the present article.

Purpura, considered by Willan as an affection of the skin, was ranked by him under the order "Exanthemata," or rashes, of his arrangement; to which it bears some affinity in external appearance only, but even in this respect does not agree with his definition of the order. Rayer has more correctly classed purpura (under the somewhat quaint name of hémacélinose,—from *αἷμα*, *blood*, *κήλις*, *spot*, *νόσος*, *disease*; *Rayer*, Malad. de la Peau, t. ii. p. 158,) under "Cutaneous and Subcutaneous Hemorrhages." But purpura cannot be correctly considered as merely a cutaneous disease, since, as Dr. Watson has well observed, "the effusion of blood (which, strictly a hemorrhage in all parts, takes the form of red or purple spots where the quantity effused is but a drop) is not confined to the skin nor to the subcutaneous tissues, but is observed occasionally on the internal surfaces also, and in the parenchymatous surface of the viscera. The disease, therefore, is properly a hemorrhage, but it is not properly, or merely, a cutaneous hemorrhage."

Purpura, considered as a hemorrhagic affection, is a most interesting subject of pathological inquiry, and demands peculiar attention from the danger which attends it, and from the obscurity which attaches to its nature and mode of cure. It has, therefore, ever since it was first distinguished from typhoid fever, attracted much notice from medical writers. For its earlier literary history, the reader must be referred to Dr. Willan's work, where he will find it amply detailed. Reference to the old writers can be of little avail for pathological and practical purposes. The first systematic account of the disease, under the name of hemorrhœa petechialis, was given in this country by Dr. Adair, in his thesis published in 1789. Dr. Bateman, in his inaugural dissertation published in 1800, described it under the same appellation. The description of purpura by Willan in his Reports of the Diseases of London, and subsequently in his great work on Diseases of the Skin, is given with his usual perspicuity, but he was practically unacquainted with the severer cases of the disease, never having met with one which proved fatal. He considered the disease as nearly if not quite identical with scorbutus, and to be combated by similar remedies. These views were disputed by Dr. Parry and Dr. Harty, and were considerably modified by Dr. Bateman in his Synopsis. Since that period a succession of valuable and instructive cases have been published in the Edinburgh Medical and Surgical Journal, and a few in other periodical works.* Yet much remains to be done ere the pathology of purpura or its treatment can be considered as satisfactorily fixed on scientific principles.

Phenomena of the disease.—These may be referred to—1. appearances on the skin; 2. hemorrhages; 3. constitutional symptoms; 4. progress and duration of the disease; 5. circumstances noticed respecting the blood and the urine; 6. morbid appearances on dissection.

1. We have already given a general description of the efflorescence on the skin characteristic of purpura. There are three different forms of it, (well represented in plates xxviii. and xxix. of Bateman's "Delineations,") viz. the P. simplex, P. hæmorrhagica, and P. urticans of Willan. The *P. senilis* of Bateman (figured in his 30th plate) is a nearly local form of ecchymosis, unattended with fever, hemorrhage, or other constitutional symptoms; we shall therefore refer to the "Delineations," and to the third and subsequent editions of the "Synopsis," for his account of it.

In the *purpura simplex*, the petechiæ are described by Willan and Bateman as occurring with little constitutional disorder. "They are most numerous on the breast and on the inside of the arms and legs, and are of various sizes, from the most minute point to that of a flea-bite, and commonly circular. They may be distinguished from recent flea-bites partly by their more livid or purple colour, and partly because, in the latter, there is a distinct central puncture, the redness round which disappears on pressure." (*Bateman*, Synopsis, p. 104.) Purpura simplex is chiefly noticed in women and delicate children. It is thus described by Heberden:—"Cutis puerorum interdùm ubique distinguitur maculis purpureis, similibus earum quæ in febribus naseuntur. Tamen cum his adversa valetudo nulla est, neque præcessit, neque subsequitur. Aliæ *pustulæ* (seil. maculæ) vix sunt semine milii majores, aliæ sunt tres polliees amplæ. Post paucos dies cunetæ, sine medicamentorum auxilio, suâ sponte plerumque recedunt. In quodam puero sic affecto, si modò digitus leviter cuti imprimeretur, continuò sanguis

ex vasis vicinis exiit, et sugillatio, tanquàm in collisis, facta est." (*Heberden*, Comment. cap. lxxviii. de maculis purpureis.) The latter circumstance is more frequently noticed in the next form of the disease.

In *purpura hæmorrhagica* "the petechiæ are often of a larger size, and are interspersed with livid stripes and patches, resembling marks left by the stroke of a whip, or by violent bruises. They commonly appear first on the legs, and at uncertain periods afterwards on the thighs, arms, and trunk of the body, the hands being more rarely spotted with them, and the trunk generally free. They are usually of a bright red colour when they first appear, but soon become purple or livid; and, when about to disappear, they change to a brown or yellowish hue; so that, as new eruptions arise, and the absorption of the old ones slowly proceeds, this variety of colour is commonly seen in the different points about the same time. (See Delin. plate xxviii. fig. 2.) The cuticle over them appears smooth and shining, but is not sensibly elevated: in a few cases, however, the cuticle has been seen raised into a sort of vesicles, containing black blood.... The gentlest pressure on the skin, even such as is employed in feeling the pulse, will often produce a purple blotch like that which is left after a severe bruise." (*Bateman*, Synopsis, p. 105.) The nature and seat of the small effusions of blood which constitute the petechiæ, from which the vibices and ecchymoses differ chiefly in magnitude, are well explained by the anatomical researches of Rayer. "On dissecting the skin," he observes, "it is found that the petechiæ and ecchymoses do not all occupy the same situation. Some are very superficial, and seated on the surface of the rete mucosum; others occupy the alveoli of the cutis; the largest and darkest-coloured have their seat under the skin in the cellular tissue. In these the blood is found coagulated, but it is fluid in the smaller and more superficial effusions. The vascular ramifications contiguous to these minute ecchymoses are in their natural state. The blood is easily removed by washing or maceration." (*Rayer*, Malad. de la Peau, ii. 162.)

The variety termed by Willan and Bateman *purpura urticans*, is comparatively rare. It is characterized by "rounded and reddish elevations of the cuticle, resembling wheals, but which are not accompanied, like the wheals of urticaria, by any sensation of itching or tingling." These little tumours gradually dilate; but within twenty-four hours or somewhat longer, subside to the level of the neighbouring cuticle. They are commonly situated on the legs, where they are intermixed with petechiæ; (see Delineat. plate xxix.;) they also appear on the thighs, breast, arms, &c. The spots are not permanent, but fade, while others appear in succession in different places. The duration of the complaint varies from three to five weeks. Willan never observed it to be attended with hemorrhage or fever; he states that it generally occurs in summer and autumn, and attacks those who are exposed to daily fatigue, &c., or young women who live luxuriously and take little exercise. Some œdema of the extremities usually accompanies it, and it is occasionally preceded by stiffness and pain in the legs. (Willan on Cutaneous Diseases, p. 461.—Bateman's Synopsis, p. 116.)

2. The hemorrhages attendant on purpura take place from the mouth, nostrils, bronchial tubes, stomach, intestines, bladder, uterus, — in short, from every part of the mucous membranes. They also in some cases occur from the skin; at least this singular hemorrhage bears in some cases a close analogy to purpura. In all these cases the effect produced on the system is from the loss of blood; but where the hemorrhage is strictly internal, as from the serous membranes or the parenchymatous substance of the viscera, the mischief is done by the mechanical compression or destruction of the texture of organs essential to life. Both cerebral and pulmonary apoplexy may thus occur and destroy the patient; of which there are several cases on record.

The most frequent hemorrhage, particularly in weak subjects, and where there is an approach to what has been termed the scorbutic diathesis, is that from the mouth. The gums are tender, and easily bleed on being touched. The lining membrane of the inside of the lips and cheeks, the investing membrane of the tongue, and also in some cases that which covers the tonsils and contiguous parts, present dark-coloured spots, which are usually elevated and distended with blood, which they pour out either spontaneously or on the slightest pressure. In some very unfavourable cases, as that related by the late Dr. Duncan, (Edinburgh Med. Journal, vol. ix. p. 405,) these spots degenerate into gangrenous ulcerations.

The tendency to the several kinds of hemorrhage varies at different periods of life: according to Rayer, epistaxis is the most common in children, as might be expected; uterine hemorrhage in women; and pulmonary or intestinal hemorrhage in male adults. The quantity of blood lost is often very considerable; and, as in other cases of hemorrhage, it is very apt to recur, and to become periodical. A case is mentioned where it returned daily at the same hour for a considerable period.

3. We have already stated that the constitutional symptoms are usually but slight in the varieties of the disease termed P. simplex and P urticans. In both of these forms, occurring without hemorrhage, considerable febrile excitement has been observed in some cases. With regard to P. hæmorrhagica, the following account of the preceding and accompanying symptoms is given by Bateman: "This singular disease is often preceded for some weeks by great lassitude, faintness, and pains in the limbs, which render the patient incapable of any exertion; but not unfrequently it appears suddenly, in the midst of apparent good health. It is always accompanied by extreme debility and depression of spirits; the pulse is commonly feeble, and sometimes quickened; and heat, flushing, perspiration, and other symptoms of slight febrile irritation, recurring like the paroxysms of hectic, occasionally attend. In some patients, deep-seated pains about the præcordia, and in the chest, loins, and abdomen, have been felt. In others, a cough has accompanied the complaint, or tumour and tension of the epigastrium and hypochondria, with tenderness on pressure, and a constipated or irregular state of the

bowels. But in many cases no febrile symptoms have been noticed; and the functions of the intestines are often natural. In a few instances frequent syncope has occurred. When the disease has continued some time, the patient becomes sallow, or of a dirty complexion, and much emaciated; and some degree of œdema appears in the lower extremities, and afterwards extends to other parts." (*Bateman*, Synopsis, p. 107.) This is a very faithful general account; but in several of the cases which have been recorded, the febrile symptoms, and those indicative of internal affections of the congestive or inflammatory kind, have been much more considerable than we should collect from Dr. Bateman's statement. Such affections are considered by Rayer as always constituting an "accidental complication" of purpura; and he says that it is only in such cases of accidental complication that he has seen it present the characters of active hemorrhage. (Op. cit. ii. 167.) On the other hand, it is to be observed that the mode of treatment which has been directed to the relief of the internal symptoms, has in several well-marked cases procured the cessation of those proper to purpura; an effect which has also not unfrequently occurred from a profuse eruption of the catamenia, (*Bateman*, Reports of Diseases of London, p. 130,) or from a hemorrhage which has appeared to be, in the language of the schools, critical. This subject, however, will more properly come to be considered under the heads of pathology and treatment.

4. "The purpura hæmorrhagica," observes Willan, "has not any regular or stated termination. It was protracted, in the cases under my own observation, from fourteen days to twelve months and upwards. The disease did not, in any of these cases, prove fatal." (Op. cit. p. 457.) In some cases the disease has proved fatal from internal or external hemorrhage, or the violence of the febrile symptoms, or prostration of the vital powers, in a shorter time, considerably, than the former period mentioned by Willan. In others it has assumed a completely chronic form, and either recurred periodically, or as to some of its symptoms been more or less constantly present. Several well-attested cases are recorded where it has appeared to be linked in an inexplicable manner with the mode of existence of the individual, and put on the character of what are properly called "constitutional hemorrhages." (See Hemorrhage.) In such cases, it has existed for years without impairment of the general health. A boy is mentioned by Bateman on the authority of the elder Dr. Duncan, whose skin for several years was constantly covered with petechiæ, and exhibited vibices or purple blotches on the slightest blow; yet he was in other respects in good health, and capable of active exercise. Pulmonary hemorrhage at length supervened, and carried him off. (Synopsis, p. 108.) A case is related by Adair, where the symptoms of purpura recurred regularly for six succeeding summers. (Diss. Inaug. p. 16.)

5. We have not been able to meet with any account of the chemical analysis of the blood in a case of purpura. Its sensible qualities, however, and mode of coagulation have been carefully noted in several cases. Dr. Watson asserts that "in many, perhaps in all instances of the disease, in which it can be examined, the blood is found actually to have undergone a change, and not merely a change which may be ascertained by nice or elaborate chemical research, but such an alteration of its sensible qualities as is evident to the eye, and forces itself upon our notice." (Watson's Lumleian Lecture, Med. Gazette, vol. x. p. 499.) The inquiry into the state of the blood is certainly one of the highest interest, both with regard to the pathology of this disease in particular, and as it bears upon the general doctrines of pathological science. But in pursuing it we must be careful to keep in view the causes which, independently of any primitive alteration in the state of the blood existing as the cause of all the phenomena of purpura, may materially affect the condition of that fluid. The coexistence of fever or inflammation will, of course, give rise to those alterations in the blood which are proper to those morbid states; accordingly we find it stated by Dr. Parry, that in both his cases the blood was highly buffed, the crassamentum firm and cohesive, but bearing a small proportion to the serum.* In other cases where the blood has been examined, there had previously occurred either very profuse or long-continued hemorrhage, which necessarily altered the quality of the blood by diminishing the quantity of the red globules as well as of the fibrine of the blood in proportion to the serum. Our conclusions ought, if possible, to be derived from the examination of blood drawn at the height of the disease, when no excessive hemorrhage has preceded, and in cases where there are no decided marks of inflammation or other disease coexisting with purpura.

Some of the most remarkable results of the examination of the blood in purpura have been the following. In the case of a sea-captain, a plethoric subject with a full pulse, the state of the blood obtained by a *second* venesection, and when purgatives had been prescribed, and two pounds of blood previously lost by epistaxis, is described by Dr. Jeffreys as follows: "The blood drawn yesterday shows an inflammatory buff on its surface, at least an inch and a half in thickness, firm and yellow, far exceeding any thing I ever saw in rheumatism or pneumonia, but not at all cupped; in fact, the whole serum looks like a corrupted coat of coagulable lymph. The crassamentum appears in a very dissolved state, of nearly a black colour, and much less in quantity than usual." (Edin. Med. Journal, viii. 435.) This patient was again twice bled, the blood presenting the same appearances; he ultimately recovered. In a case related by Dr. Johnston, of decidedly febrile character, and which rapidly proved fatal, the blood did not separate into serum and crassamentum; it had little consistence or tenacity, but traces of coagulable lymph were diffused through it. (Edin. Med. Journal, xviii. 402.) In Dr. Duncan's case, which has been already quoted, the blood, while flowing slowly from the vein, was

* Edin. Med. Journ. v. 8. In a case related by Bateman, (Reports on Diseases of London, p. 131,) of purpura occurring in a stout farmer, with a sharp and frequent pulse, the blood also exhibited a firm buffy coat.

observed to be florid and semi-transparent, resembling diluted arterial blood. It slowly formed a loose coagulum, from which no serum was separated; the coagulum was like jelly, tremulous, transparent, and colourless, the few red globules having subsided to the bottom. In this case much blood had been previously lost by hemorrhage. (Ibid. xviii. 405.) In Dr. Combe's case the blood was pale, coagulated slowly, separated no serum, and was not buffed. (Ibid. xvii. 83.) In Dr. Gairdner's the blood first drawn by the lancet seemed, four hours after, to coagulate very imperfectly into a homogeneous mass. On the following day it resembled a tremulous jelly, the top of which was of a greenish buff colour with brownish spots like tadpoles. What afterwards oozed from the puncture resembled turbid lymph, or a watery fluid containing colouring matter in suspension; the cloths taken from the arm appeared as if stained with bloody water. (Edin. Medico-Chir. Transactions, i. 671.) In Dr. Fairbairn's case the blood first drawn resembled that described by Dr. Duncan and Dr. Combe; on a second bleeding it presented the same appearances; but on the third it showed the buffy coat, coagulated somewhat more firmly, and separated a portion of serum. (Ibid. ii. 671.)

[These facts do not accord with the recent views of Andral, (*Hématologie Pathologique*, Paris, 1843, or translation by Drs. J. F. Meigs and A. Stillé, Philad. 1844,) that the fibrinous element of the blood is probably depressed beneath its normal proportion in every case of purpura hæmorrhagica.]

The state of the urine has been less attentively noticed, or at least less frequently. We possess, however, the accounts of two cases in which the urine has been analyzed. At the conclusion of Dr. Combe's case, which we have just referred to, the results of the analysis of the urine are stated, at the height, during the decline, and after the cessation of the disease. At the height of the disease, and previous to venesection, the urine was found to contain a large proportion of serosity and of the phosphates, no free acid, and but a small proportion of urea. When the force of the disease had been broken, and the hemorrhage had ceased, there was no longer any albuminous matter, but a free acid, and but a small proportion of urea. Finally, when the patient was convalescent, the analysis of the urine detected no ingredients differing from its healthy condition. In Dr. Gairdner's case, also above referred to, the urine, on analysis by Mr. Murray, showed a deficiency of urea and an excess of albuminous matter. For the chemical details we must refer to the original cases. In Dr. Blackall's work on Dropsy, several cases are related "resembling land-scurvy," two of which, at least, are clearly cases of the hemorrhagic purpura, in which the attack was sudden and attended with febrile symptoms. In both these cases the urine was albuminous, and Dr. B. states his opinion that "venesection would have been their appropriate remedy; in the early stage, probably a successful one."

6. The appearances which are exhibited by the skin on examination after death have already been noticed. Of the morbid alterations discovered in the internal organs we possess a tolerable number of histories, recorded with various degrees of minuteness.*

The chief morbid appearances which have been noticed in the three great cavities have been the following:

In the *head*. In a case transcribed by Rayer (Obs. 174,) from Stoll, the meninges of the brain, especially on the left side, were spotted with several large ecchymotic maculæ; some ecchymoses, resembling clots of extravasated blood, from the size of a lentil to that of a bean, were also found in the convolutions of the brain. The surface of the ventricles, and that of the cerebellum, were covered with innumerable small petechiæ; the left ventricle was distended with straw-coloured serum. The girl who was the subject of this case had died comatose, having previously suffered severely from headach (which chiefly affected the left side); she had high fever, petechiæ, and hemorrhage from the mouth. In Dr. Walsh's case (Edin. Med. Journ. vol. ix.) of a soldier previously in good health, who died apoplectic on the fourth day from the supervention of purpura hæmorrhagica, besides the impression of petechial spots on the pericranium, and an ecchymosis of the right temporal muscle, a considerable coagulum (a table-spoonful) was found pressing on the brain, and the vessels of the pia mater were turgid with black blood. In Mr. Wood's case (Edin. Medico-Chir. Trans. vol. i.,) the pericranium and dura mater were covered with petechial spots, and "in the right temporal region a fine coagulum, floating in bloody serum, had forced its way through the broken-down brain into the ventricle." Similar effusions of blood on the brain were observed in two cases by Dr. Watson. (Med. Gazette, x. 502.)

In the *chest* the following appearances are noticed by Rayer as characteristic of this disease. "The outer surface of the lungs is commonly speckled with numerous ecchymoses, which are the more distinctly visible, that the surface of the lung in the intervals retains its natural hue. Beneath each of these ecchymotic spots the tissue of the lung is of a uniform brownish-red colour, is firmer in its texture than the surrounding healthy lung, and presents a circumscribed engorgement, from which, on pressure, black blood is squeezed out—a morbid alteration quite analogous to the hemoptysical engorgements described by Laennec." Similar petechial spots are also found on the surface of the heart, on the pleura, &c. The other morbid changes noticed in the thorax are not so characteristic, being common to other diseases. Such are the effusions of serous or sero-sanguineous fluid very commonly found in the cavities of the pleuræ or pericardium, or in the cellular tissue of the lungs. In one case (Dr. Johnston's) the heart is stated to have been small, pale, and easily lacerable. In some cases it has contained fluid blood, or pink-coloured gelatinous coagula in some of its cavities. The pericardium, in one case, and the inner membrane of the aorta

* *Raymann*, Acta Nat. Cur. apud Adair, diss. inaug. p. 14. Edinburgh Med. Journal, vi. 374. Ibid. ix. 164 Ibid. xiii. 402. Ibid. xiii. 405. Ibid. xxvii. 71. Edinburgh Medico-Chir. Trans. i. 681. Ibid. ii. 161. *Rayer* Malad. de la Peau, tome ii. observ. 171, 172, 173, 174 175. Cases 173 and 174 are transcribed from Stoll, Ra Medendi.

in another, showed a blush of redness. In a boy who died ten days after the supervention of purpura, Dr. Bateman found a large firm tumour occupying the situation of the thymus gland; this tumour, which must have been of slow growth, had not perceptibly affected the respiration or impaired the general health. Tubercles of the lungs were found in a case mentioned by Rayer, (Observ. 171); and pulmonary tubercles, and the marks of chronic inflammation of the substance of the lungs, were met with in another case in a child seven years old. But this case, in which petechial spots and epistaxis supervened only on the day of the child's death, and as a symptom of impending dissolution, ought not to be taken as a fair instance of purpura.

In the *abdomen*, petechial and ecchymotic spots are often found throughout a considerable tract of the mucous membrane of the alimentary canal, especially in the stomach, duodenum, and upper part of the small intestines, but sometimes also in the colon. Similar spots are also met with underneath the serous membranes, as betwixt the folds of the mesentery, and under the peritoneal covering of the viscera. Dr. Fairbairn found the cardiac extremity of the stomach emphysematous, (which did not arise from putrefaction,) the liver and spleen somewhat softened, and a bloody fluid could be squeezed from their substance; one kidney was also softened. A case is related by Dr. Bateman, where the spleen had been felt during life nearly as low as the spine of the ileum, and after death was found enormously enlarged. (Synops. p. 112.)

[Under another head (Spleen, Diseases of the) reference is made to "splenic cachexia," as it is termed in India, which is accompanied by all the signs of purpura, and which is evidently connected with, and perhaps dependent upon, hypertrophy and atrophy of that viscus. Not long ago the writer had a fatal case of this form of diseased spleen under his care, in which the organ was greatly enlarged, and encephaloid in certain portions. All the signs of purpura hæmorrhagica supervened, with hydropic infiltration of the lower extremities, under which the patient died. In another case of purpura, that fell under his care, the spleen was sound, but the liver was scirrhous, and incurable jaundice preceded the fatal termination.]

Predisposing and exciting causes.—Purpura generally may be stated to be rather a rare disease; it is especially so in its more severe forms. The purpura simplex most commonly affects children; cases resembling purpura urticans, but often presenting anomalous symptoms, occur chiefly in young women. Of seventeen cases of purpura hæmorrhagica, which were all that Dr. Willan had met with, two only were men, nine women, three boys, and three infants under a year old; four of the women were above the age of fifty. The proportion of male adults is considerably greater in the cases which have been recorded subsequently to the publication of Willan's work, especially in the severe and fatal cases.

Willan, Bateman, and Rayer agree in stating that purpura chiefly occurs in individuals of delicate habit, or enfeebled by their occupations or mode of life; by confined, low, or damp habitations, scanty food, hard labour, grief, anxiety, fatigue, and watching; or who have suffered from acute or chronic disease. In a case mentioned by Willan, it ensued on excessive drinking of undiluted spirits. (Reports on Diseases of London, p. 167.) In a fatal case which occurred to Bateman, it came on during a severe salivation, accidentally induced by a few grains of mercury. (Synopsis, p. 110.) A remarkable case is related in the appendix to Adair's Thesis, of a Hampshire farmer, aged 34, who was hereditarily predisposed to insanity, and becoming affected with religious melancholia, refused all food and drink except bread and water. After having some time subsisted on this diet, symptoms of purpura or scorbutus supervened; viz. petechiæ all over the body, accompanied by remarkable roughness of skin, a large ecchymosis above the right ham, gums tender, swollen, and bleeding, legs œdematous, pale dejected countenance, great debility, stiffness of the joints, (which preceded the petechial eruption,) oppressed respiration, bowels costive. This patient recovered under the use of vegetables and ripe fruits, for he could not be persuaded to take animal food.

On the other hand, purpura frequently occurs where no causes of a debilitating or depressing nature can be supposed to have existed; in persons in the prime of life, in the easy and opulent classes of society, breathing a pure air, and enjoying the necessaries and comforts of existence. "This circumstance," observes Bateman, "tends greatly to obscure the pathology of the disease; for it not only renders the operation of the alleged causes extremely questionable, but it seems to establish an essential difference in the origin and nature of this disorder from that of *scurvy*, to which the majority of writers have contented themselves with referring it. In scurvy, the tenderness of the superficial vessels appears to rise from deficiency of nutriment, and the disease is removed by having recourse to wholesome and nutritious food, especially to fresh vegetables and to acids; while in many cases of purpura the same diet and medicine have been taken abundantly without the smallest alleviation of the complaint. In other cases, where a residence in the country, and the circumstances of the patients necessarily placed them above all privation in these respects, the disease appeared in its severest degree." (Synopsis, p. 110.)

Pathology of Purpura.—If the opinion just adverted to of the identity of purpura with true scurvy were admitted, it would not be necessary to enter into any particular inquiry respecting the pathology of the former disease, as distinct from scorbutus. Dr. Willan seems to have entirely acquiesced in that opinion. "I consider it (purpura), under all the forms described, as pertaining to the scurvy; though it is not always attended with sponginess of the gums and a discharge of blood from them, according to the definition of scorbutus in nosology." (*Willan*, p. 466.) Into the nature and causes of scorbutus we are not to enter in this place; not only because we can say nothing satisfactory of a disease which we have never seen, and which is now happily rarely to be met with ever by naval

practitioners, but because it will form the subject of a separate article in this work. We are, however, inclined to acquiesce in the opinion of Bateman and of most succeeding writers, that purpura (at least many cases of it) is distinct in its nature, causes, and mode of treatment, from the true scurvy described by Lind, Trotter, &c. and as we conceive there can be no doubt of the truth of Cullen's doctrine, "that there is one disease only entitled to the name of scurvy; that it is the same by land as upon the sea, depending every where upon the same causes," (First Lines, sec. 1790,) it appears to us that the name of *landscurvy*, as a synonym for purpura, (Good's Study of Med. vol. ii. p. 875, and Syst. of Nosology, p. 268,) is improper, and calculated to lead to an erroneous notion of the latter disease.

The late Dr. Duncan enumerates the following as the possible modes in which he conceives the phenomena of purpura might be produced:—1. increased tenuity of blood, allowing it to escape from the extremities of the capillary arteries; 2. dilatation of the mouths of these arteries, allowing natural blood to escape; 3. tenderness of the coats of the minute vessels, giving way from the ordinary impetus of the blood; 4. increased impetus of the blood, rupturing healthy vessels; 5. obstruction in the vessels causing rupture; 6. two or more of these causes acting simultaneously or successively. But he acknowledges that he cannot reconcile any of these suppositions with the phenomena of the disease. (Edin. Med. Journ. ix. 410.) Other recent writers equally confess their ignorance of its true pathology. Of the intimate nature of the process by which the blood is poured out at once from the capillaries of the cutaneous surface, and of the internal organs, we must probably be content to remain ignorant, until the *physiological* action of that important part of the vascular system shall be better understood than it is at present. Many processes, both natural and morbid, are not more explicable than the occurrence of petechiæ, either as a symptom of fever, or from other causes; and especially the process of *hemorrhage by exhalation*, of the close connection of which with the phenomena of purpura there can be no doubt.

The most striking peculiarity of purpura, considered as a hemorrhagic disease, is the *universality* of the hemorrhagic tendency, whereby the blood is poured out not only from the various mucous membranes, at least from several of these outlets, simultaneously or in succession, but is also effused into the textures of the skin and cellular membrane, forming petechial spots, and occasionally into the serous cavities or the texture of the solid viscera. It is, therefore, a very probable, if not a certain conclusion, that the immediate cause of these phenomena is one affecting the whole system; and none seems so probable, or so well accords with the phenomena, as *an alteration in the composition and vital properties of the blood.* When we take into consideration the analogy which subsists between the phenomena of purpura and those of petechial fever on the one hand, and of cachexy, passive hemorrhage, and scorbutus on the other, it is highly probable that a similar cause is in operation in all these cases. In scorbutus it is generally admitted that the composition of the blood is vitiated. That a change both in its composition and its vital properties is intimately concerned in the production of the phenomena of fever, is a conclusion the proofs of which are rapidly accumulating upon us. (See the articles Fever, and Morbid States of the Blood, in the present work.) We have, therefore, strong analogical grounds for believing that a like cause is productive, at least in some cases, of that assemblage of symptoms to which we give the name of purpura. The proofs of this opinion will be found fully and very ably developed in Dr. Watson's Lecture on Purpura, (Medical Gazette, vol. x. p. 498,) to which we refer the reader.

The third hypothesis suggested by Dr. Duncan, viz. weakness or frangibility of the coats of the capillary vessels, has several facts to support its probability, and especially the tender state of the gums, and the readiness with which blotches and ecchymoses are produced in some cases by the slightest pressure on the skin. Such a state may coexist with a primary diseased condition of the blood, and may be induced by the circulation of such blood through these vessels, which is not improbable; though, as Dr. Watson has suggested, the relation of cause and effect may be different from this: "It is easy to imagine that some derangement (of the nature of which, supposing it to exist at all, we know nothing) in that part of the circulating system which is strictly capillary, and in which those changes take place whereby the blood, from being scarlet or arterial, becomes purple or venous, should modify or interfere with the change itself, and so come to affect the quality of the blood." (Medical Gazette, vol. x. p. 499.)

But to whatever conclusion the pathologist may come on these points, it cannot affect the practical fact, that purpura is not unfrequently connected with a state of the system at large, or of particular organs, which not only will bear, but requires depletory measures for its removal, and which renders the use of tonic and stimulant remedies improper and dangerous. Of this the recorded cases of the disease supply abundant evidence. "The rapidity of the attack," observes Dr. Bateman, "the acuteness of the pains in the internal cavities, the actual inflammatory symptoms that sometimes supervene, the occasional removal of the disease by spontaneous hemorrhage, the frequent relief derived from artificial discharges of blood and from purging,—all tend to excite a suspicion that some local congestion or obstruction is the cause of the symptoms in different instances." (Synops. p. 111.)

Diagnosis.—The diseases with which purpura is most likely to be confounded are, typhous fever attended with petechiæ, and scorbutus. Where the symptoms denoting purpura are accompanied by febrile symptoms of some intensity, it may become a question whether the purpura or the fever be the primary disease. The origin and course of the complaint, the period at which the petechiæ appear, the extent and the variety of the accompanying hemorrhages, will enable the practitioner to judge of the nature of the case. With regard to scorbutus, that disease is now fortunately seldom if ever to be met with in its genuine form. Cases of petechial efflorescence attended with he-

morrhage and signs of great general debility, without any febrile or inflammatory symptoms, may be considered by some practitioners as properly belonging to scurvy; and if they occur in patients who have been much exposed to the influence of debilitating causes, the tonic treatment appropriate to that disease, and especially pure air and an improved diet, will generally be beneficial.

Prognosis. — In the milder cases of purpura, which are unattended by hemorrhage, by any considerable febrile symptoms or organic disease; or where the hemorrhage is slight, or attended with amelioration of the symptoms; a favourable prognosis may be formed. But when much blood is lost by the profuse occurrence or long continuance of hemorrhage, or where there are symptoms of serious internal congestion or inflammation, high fever, or great depression of the vital powers, the prognostic is unfavourable. Even in chronic and *constitutional* cases a guarded prognosis should be given, and the danger of the supervention of fatal hemorrhage should not be lost sight of.

Treatment.—While the older doctrines prevailed, which ascribed the symptoms of purpura solely to debility of the solids and attenuation of the blood, a tonic and invigorating treatment was universally recommended. The mineral acids, cinchona, and wine, comprehended the whole medicinal treatment; these, however, were acknowledged to be often merely palliative, and to have little effect in producing a radical cure. (*Adair*, Diss. Inaug. p. 18.) The same remedies are alone mentioned by Willan, who at the same time insists strongly on the importance of pure air, exercise, good diet, and whatever may tend to produce cheerfulness and serenity of mind. (*Willan*, Reports, p. 93; Cutan. Dis. p. 461.) Willan's experience of this disease had not been extensive; and in particular its more severe and fatal forms had not occurred to him. The publication of his opinions respecting this disease and its treatment called forth the observations of Dr. Parry on the utility, in some cases, of venesection. (Edinb. Med. Journ. v. 7.) Dr. Harty and Dr. Bateman subsequently called the attention of the profession to the benefit to be derived from the employment of purgative medicines. Dr. Harty having experienced a complete failure in a case of purpura hemorrhagica which he treated strictly according to the plan of Willan, with every advantage of country air, nourishing diet, and tonics, had his attention turned to the functions of the alimentary canal in this disease. In a seemingly very unfavourable case of purpura hemorrhagica, in a tedious and obstinate case of purpura simplex attended with fever and headach, and in nine others, he employed brisk purgation with decided success. (Edin. Med. Journ. v. ix. p. 186.)

Dr. Bateman, after admitting that in slighter degrees of purpura, occurring in women and children who have been under the influence of close air, want of exercise, and other debilitating causes, the tonic plan, as recommended by Willan, may be adequate to the cure of the disease, adds :— "But in adults, especially those already enjoying the benefits of exercise in the air of the country, and who have suffered no privation in respect to diet; or when it appears in persons previously stout, or even plethoric; when it is accompanied with a white loaded tongue, a quick and somewhat sharp, though small, pulse, occasional chills and heats, and other symptoms of feverishness, however moderate; and if at the same time there are fixed internal pains, a dry cough, and an irregular state of the bowels, — symptoms which may be presumed to indicate the existence of some local congestion,—then the administration of tonic medicines, particularly of cinchona, wine, and other warmer tonics, will be found inefficacious, if not decidedly injurious. In such cases, free and repeated evacuation of the bowels, by medicines containing some portion of calomel, will be found most beneficial. The continuance or repetition of these evacuants must, of course, be regulated by their effects on the symptoms of the complaint, or on the general constitution, and by the appearance of the excretion from the intestines. If the pains are severe and fixed, and if the marks of febrile irritation are considerable, and the spontaneous hemorrhage not profuse, local or general bloodletting may, doubtless, be employed with great benefit, especially in robust adults." (*Bateman*, Synops. p. 114.) We have given Dr. Bateman's practical directions at length, because little has been added to them by subsequent writers, except in the way of illustration. We apprehend that in very few cases will tonics be requisite or admissible, at least at the commencement of the disease. We have seen them do evident mischief, even in children of delicate frame, in whom the cautious but effectual employment of laxatives and a mild antiphlogistic regimen have afterwards effected a cure. From the manifest success of purgatives, and especially calomel, in the congestive form of typhous fever attended with petechiæ, practitioners have learned not to be deterred by the symptoms of apparent debility from employing this most useful class of remedies in such fevers; and in purpura, notwithstanding similar signs of prostration of strength, they are no less efficacious.

Venesection is a more hazardous remedy, and requires greater discrimination as to the cases and period of the disease in which it probaly may be employed with safety and advantage. In the circumstances pointed out by Bateman, and especially where there is hardness of pulse and fixed local pain, there can be no doubt of the propriety of having recourse to it, especially at an early period of the disease. But we must be very cautious not to push it too far, or employ it too late to be of benefit. Dr. Mackintosh informs us that he lost a patient some hours after she had been bled; and the subject of Dr. Fairbairn's case, though a strong man in the prime of life, never rallied after the third bleeding. Dr. Fairbairn candidly confesses that he doubts whether the bleeding was not carried too far. In other cases which have been treated by venesection, but where, from the symptoms of debility or supposed putrescent tendency, wine and other stimulants have been administered, it is much to be suspected that these have proved injurious, and that if a mild antiphlogistic regimen had been trusted to, the result might have been more satisfactory.

In conclusion, we may sum up by observing that, in the treatment of cases of purpura, we are not to be guided by the name or the external appearances of the disease, but by diligent attention

to the symptoms, and especially to the state of the functions, and the habit and constitution of the patient. Where high excitement prevails, with strength of pulse and vigour of constitution, and we have reason to suspect inflammation, or an approach to it, venesection and free purging, with a suitable antiphlogistic diet, are the appropriate remedies. Where a quite opposite state exists, extreme languor and debility, pale cachectic complexion, small and weak pulse, and much hemorrhage has occurred, all active depletion must be abstained from, and the strength supported by beef-tea and other mild nutriment, while sulphuric acid, and perhaps divided doses of quinine, may be resorted to. In intermediate cases, a mixed treatment must be adapted to the exigencies of the particular case by the discrimination of the practitioner. It will be often much safer in such cases, where any doubt exists as to the proper plan of treatment, to adopt one almost purely negative, as saline diaphoretics and a mild antiphlogistic diet, (paying due attention to the bowels,) than to have recourse to any extreme measures.

Local hemorrhage, when trifling in its amount and occurring early in the disease, it may not in all cases be advisable to interfere with. It has in several well-attested cases appeared to be a salutary effort of nature, and has removed the symptoms of the disease. Where the hemorrhage is protracted, or dangerously profuse, the usual means (pointed out in the article Hemorrhage, and in those which treat of the individual hemorrhages) must be had recourse to to arrest it; and of these there is none so generally efficacious as the application of cold.

Some particular modes of treatment have been recommended in this disease, of which we cannot speak from experience, and therefore we shall merely refer to them. The oil of turpentine was employed with success by Dr. Nicholl in several cases of purpura unattended with fever, and which he conceived to depend on mere relaxation of the extreme vessels. A successful case of its employment has since been published by Dr. Magee; but it should be noticed that both these physicians employed it in combination with laxatives. Dr. Mason Good and Dr. Mackintosh recommend the vegetable acids in purpura, in preference to the mineral; the latter especially speaks in favour of "fresh lime-juice, not only taken internally, but applied externally." Spirit-lotions, or a solution of chloride of lime, or cloths dipped in vinegar and water, are advised by Rayer to be applied to those parts of the skin which are spotted with petechiæ and ecchymoses; we confess we do not understand on what principle.

Dr. Belcombe, physician to the York County Hospital, has recently applied with success to this disease the principles of treatment which Dr. Stevens has advocated in certain diseases conceived by him to depend on a morbid deterioration of the blood, and especially in the fevers of hot climates and in epidemic cholera, namely, the administration of neutral saline remedies, not intended to act as cathartics. In a decided and severe case of purpura hemorrhagica, in which Dr. Belcombe adopted this treatment, according to the formula of Dr. Stevens, (bicarbonate of soda ℥ss, muriate of soda ℈i, chlorate of potass gr. vii.;) the result was the recovery of the patient; and in two other cases of petechial eruption which have since occurred to him, he has had recourse to it with the same success.

George Goldie.

PUS, (from *πύον, matter,*) a yellowish-white, bland, cream-like fluid, having a sweetish taste and faint smell, heavier than water, (Sp. gr. about 1.03,) found in abscesses, on the surface of ulcers, and occasionally deposited on free surfaces, or in the tissue of organs.

An account of the various opinions entertained of its formation, as well as a description of its physical and chemical properties, will be found under Abscess, Inflammation, and Suppuration.

A. Tweedie.

PYLORUS, DISEASES OF THE.—See Stomach.

PYROSIS, (Gr. *πύρωσις, burning, inflammation;* from *πυρόω, to burn;* th. *πῦρ, fire.*)—This is the generic name of a disease adopted into their nosological classifications by Sauvages, Sagar, and Cullen, and, according to the definition of the last mentioned writer, synonymous with the cardialgia *sputatoria* of Linnæus and Mason Good. Sauvages has defined it, "Sensus ardoris in ventriculo et œsophago sine febre acutâ;" and Sagar, "Ardor œsophagi ad ventriculum usque extensus sine febre, vulgo soda dicitur;" both corresponding to the character of soda in the system of Vogel, formerly a common but now obsolete name for *heartburn.* But the peculiar combination of symptoms which the early writers on medicine had included in their general descriptions of gastric disorder, particularly under the term cardialgia, and which previous nosologists had classed as one of several species of the same genus under the generic name of pyrosis, Cullen was the first to consider as the indications of a distinct idiopathic disease, which he separated accordingly, and placed in his class Neuroses, and order Spasmi, with the following definition, "epigastrii dolor urens cum copia humoris aquci, plerumque insipidi, aliquando aeris, eructata." Such has been the general and limited acceptation of the word pyrosis in this country since the time of Cullen, and the signification we attach to it in the present article.

This form of disease is known in England by the popular name of *black-water,* and in Scotland by that of *water-brash.* It is most frequently to be observed amongst the poor, but sometimes, though rarely, in persons of more fortunate condition in life. In Scotland, Lapland, and Iceland, it has been observed to be endemic, and probably is a prevailing disease in many other countries; in England it is strictly sporadic. The subjects of it are most commonly persons under middle age; it seldom appears before puberty, and very rarely in advanced life. Females are more often affected with it than males, sometimes during pregnancy, and occasionally it seems incidental to this state, subsiding when it terminates, and recurring with its repetition. It most frequently, however, occurs in the unmarried, and of the married, most frequently in those who have never been pregnant: in many instances it appears when leucorrhœa has been present. Having once taken place, it is apt to return for a long time after; and though often

extremely difficult to cure, is seldom if ever directly attended with danger to life.

The **Causes** by which it has been induced have never been satisfactorily determined; but the facts of its endemic occurrence, its almost exclusive prevalence among the lower classes of the community, even where it is only sporadic, as in this country, and regard to the functions of the particular organ which appears to be chiefly implicated, have raised a prevailing belief that the ingesta have a powerful influence on its production. It was remarked, however, by Cullen, that he had not observed its connection with any particular diet, and that persons using animal food were subjects of it, although he thought more frequently those whose subsistence was milk and farinaceous substances. In Scotland, however, (the field, be it remembered, of Cullen's observations,) unfermented meal forms the bulk of the diet of the poor; and up to the present time the same substance in the form of oat or barley cake has stood as an article in the diet of the great mass of the people, in the same relation as wheat bread to the diet of the people of this country. The similar use of other articles of food defective in its nutritious quality, and difficult of digestion, has been commonly observed to precede its occurrence, and in those whose idiosyncrasy predisposes them to be so affected, (a condition of which we acknowledge our entire ignorance,) all those circumstances which obstruct the natural functions of the stomach are, more or less, conducive to the development of pyrosis.

In some instances the use of indigestible substances has appeared to us to have been an *exciting* cause of the attack; but those which are most generally considered so, are suddenly diminished temperature, particularly in the application of cold to the feet, and extraordinary emotions of the mind.

The paroxysms of pyrosis, according to Cullen, (whose description of the symptoms has been considered most faithful,) usually come on in the morning and forenoon after food has been abstained from for some hours, though in our experience the period has not uncommonly been two or three hours after dinner: its first symptom is a pain at the epigastrium, described as that of extreme heat (emphatically called by the French *fer chaud*,) with a sense of constriction, as if the stomach were drawn towards the back, the pain being greatest when the body is in the erect posture, and causing it to be bent forwards; it is often very severe, and after continuing for some time is followed by an eructation of thin fluid, varying in quantity, but in appearance always resembling water; to the taste it is often absolutely insipid, but sometimes extremely sour. Though apparently the occasion of a sense of extreme heat in the stomach and œsophagus, the ejected fluid in passing through the mouth occasionally impresses it with an opposite sensation of cold in a very remarkable degree. The eructation is frequently repeated, and the pain which preceded it does not immediately cease, but does so after a time, and terminates the paroxysm. These paroxysms vary in their duration, both in the same and in different individuals, recurring often successively every day for a considerable time, and sometimes intermitting for one or several days, but always with great irregularity. Cullen has declared that pyrosis is often unattended by any symptoms of dyspepsia, but the remark is not only inconsistent with his own definitions of the two diseases and his observations upon them, but (we presume to say) with general experience. That the symptoms vary in number and degree we doubt not, but their entire absence we conceive to be extremely rare: one which has appeared to us to have been almost invariably present has been pain at the epigastrium immediately consequent to swallowing any ordinary food. We are, moreover, without proof or reason of probability that the morbid condition of the stomach which gives rise to pyrosis differs in any essential degree from that which occasions some other forms of dyspepsia, certain variations in the phenomena of which are as much beyond our explanation, as the specific distinctions by which they are severally characterized. The distinguished writer we have so frequently had occasion to cite, seems indeed to have been unconscious of the approximation of his own ideas on this point in reference both to dyspepsia and pyrosis, having defined the proximate cause of dyspepsia, "an imbecility, loss of tone, and weaker action in the muscular fibres of the stomach," and spasm (which can be viewed in no other light than a consequent condition, and of the same structure), as the proximate cause of pyrosis. "It seems," says he, "to begin by a spasm of the muscular fibres of the stomach, which is afterwards in a certain manner communicated to the blood-vessels and exhalants, so as to increase the impetus of the fluids in these vessels while a constriction takes place on their extremities. While, therefore, the increased impetus determines a greater quantity than usual of fluid into these vessels, the constriction upon the extremities allows only the pure watery parts to be poured out, analogous in every respect to what happens in diabetes hystericus." Another and opposite view has been suggested by Mason Good, who considers that in some instances pyrosis may be induced by a peculiar paresis or inactivity of the proper absorbents of the stomach,—an hypothesis founded on some experiments of Magendie, proving the rapidity of the absorption of fluids from the stomach in a state of health, even when its pyloric orifice has been encircled by a ligature; but the absorption of other fluids, and the regurgitation only of the morbid product, reflect a degree of improbability on this conjecture. We are, indeed, without any evidence that the latter is actually secreted by the stomach, and it has been surmised, from the resemblance between the natural secretion of the pancreas and the ejected fluid, that it may be derived from this source: the writer, however, is not aware that the latter has been submitted to chemical analysis, but the result of this process promises means of comparison whereby the supposition would be further confirmed or invalidated. *A priori* it appears impossible that a fluid so uncongenial to the sensibility of the stomach should be admitted into it by an inversion of the natural action of the duodenum without more violent efforts than are manifested, or that the fluid itself proceeding from this source should appear entirely free from any admixture of bile

[The writer is disposed to regard it as a form of gastrorrhœa. In some persons, the secretion is so copious, that they can eject at pleasure considerable quantities of fluid, especially in the morning before taking food,—or they possess what has been termed the faculty of *vomiting at pleasure*. (See the article INDIGESTION, vol. ii. p. 639.)]

Prognosis.—Pyrosis in its simple form is never attended with danger to life, nor does it commonly even prevent the sufferer from pursuing his ordinary occupation. The physician, however, is frequently baffled in his attempts to cure it, and even when there has been a reasonable hope of the remedial means having been successful, a recurrence of the watery eructation has not unfrequently exposed its fallacy.

Treatment.—The doubt in which our knowledge of the pathognomonic causes of pyrosis is involved, obscures the indications on which the method of treating it should be grounded and pursued with a rational anticipation of success; nor has observation even up to the present period in any satisfactory degree supplied the deficiency. Opium will certainly relieve the paroxysm; and its various preparations, as well as other anodynes and antispasmodics, as hyoscyamus and conium, with camphor, the compound spirit of sulphuric ether, and the aromatic spirit of ammonia, variously selected and combined according to the peculiarities of the circumstances of the patient, will all be found useful for this purpose, but relief of the paroxysm appears only to be a temporary advantage: to render it permanent, the intermediate state must be the object of our more particular consideration. We have the warrant both of reason and experience for concluding that digestion cannot be perfectly accomplished whilst the functions of an organ so important to it as the stomach are subject, whether primarily or secondarily, to the frequent interruptions occasioned by the accessions of this disease. A morbid state of the pancreas we know also will materially obstruct this process. The regulation, therefore, of the diet is a most essential point in the plan of treatment; all substances which are likely to ferment are difficultly digestible, and manifestly productive even of temporary discomfort or uneasiness, and the farinacea should as far as possible be avoided. It might be even advantageous, and especially when the disease is endemic, to effect an entire change in the articles which have constituted the general diet, so regulating the quality and limiting the quantity as if the cure of indigestion, whether evident or not, were the object to be effected. Any deviation from the natural state in the functions of the liver or alvine canal should be corrected by remedies appropriate to their particular condition; but in the special plan of the treatment of pyrosis, it will be found advantageous occasionally to produce a laxative effect on the latter, and for this purpose aperients which occasion a sense of warmth in the stomach have been found most suitable; such, for instance, as the compound decoction of aloes, combinations of the powder of rhubarb with magnesia, the compound tinctures of rhubarb and cardamoms, and peppermint-water, the powder and compound tincture of rhubarb, with carbonate of ammonia and camphor mixture, &c. It has further been the practice pursued to attempt to restore the supposed loss of tone in the muscular fibres of the stomach, and at the same time to neutralize the acid secretions which are commonly present. The particular medicines used with this view have been various combinations of the vegetable tonics with aromatics, and large doses of alkalies and the alkaline earths; of the former, particularly the carbonate of ammonia and its preparations. Tonics of the same kind with the mineral acids, particularly sulphuric, have also been recommended for this purpose. The various preparations of iron and zinc have also been had recourse to, but we believe it to be the result of general experience, as it has been of our own, that however such means may have counteracted any other coexistent symptoms resulting from dyspepsia, or have mitigated or suspended the painful accessions which constitute this affection, its recurrence has too often taken place as usual.

Cullen distinctly states that all the remedies for the cure of indigestion have been applied to it without success, and the late Dr. Baillie has left it on record that, consistently with his experience, it had been little benefited by medicine. He added, however, that a drachm of compound tincture of benzoin rendered miscible with water by trituration with mucilage, he had found the most efficacious of any. (Lectures and Observations on Medicine, by the late Matthew Baillie, M. D., 1825.) We know it to have been also a favourite prescription of another experienced eminent physician in the treatment of pyrosis. Astringents, such as the compound powder of kino given three times a day in doses of ten grains, have been considered serviceable in cases of dyspepsia in which pyrosis has been a prominent symptom. Linnæus, who had frequent opportunities of witnessing the disease, recommended the nux vomica for its relief, in doses of ten grains three times a day; but this has been regarded, and doubtless is, a very hazardous quantity to commence with. We are not aware that strychnine has been substituted for it; but the preceding recommendation points it out as worthy of trial, in doses of from a twelfth to a sixth of a grain every eight hours. The subnitrate of bismuth, suggested as a remedy in cases of gastrodynia and other painful affections of the stomach by Dr. Odier of Geneva, and favourably reported of by Dr. Marcet in the fifth volume of the Memoirs of the London Medical Society, in similar cases, was particularly recommended as a useful medicine in the cure of pyrosis by Dr. Bardsley of Manchester, in his "Medical Reports of Hospital Practice," published in the year 1807. His recommendation is accompanied with a detail of several cases in which its use was successful; and with the comment, that in pyrosis and disorders of the same kind it exerts a local and specific action upon the organs of digestion, restoring the stomach to a state of vigour and consequent healthy secretion, essential to the removal of the symptoms of acidity, spasm, and pain. Dr. Bardsley prescribed it in doses of five grains with from fifteen to twenty grains of compound powder of tragacanth, two or three times in the day; a mode which we have found useful in similar cases. Dr. A. T. Thomson speaks highly of it in combination with extract of hops, having found it, as he states, extremely beneficial

in pyrosis, gastrodynia, and some other varieties of dyspepsia; and when there has been merely atony of the digestive organs without organic mischief, almost universally successful. Mason Good has spoken in high commendation of the internal use of soap in pyrosis, combined with opium if it should be attended with much pain; he refers the efficacy of the former to its decomposition allowing the alkali to unite with the acrid secretion, whilst the oil defends the stomach from the action of any acrimonious matter which may be present. He has not, however, mentioned the quantity or form in which he has prescribed it; but from the benefit we have known it to produce with rhubarb and extract of gentian in some of the modifications of dyspepsia, we should be inclined to adopt a similar combination in prescribing it for the cure of pyrosis. On the principle of allaying irritation, and thereby favouring a slower, and consequently more healthy gastric secretion, hydrocyanic acid has been recommended for the relief of pyrosis; but experience is yet required to determine whether it possesses any lasting power over it. The decided advantage derived from its use in cases apparently allied to pyrosis, leads us to anticipate that it will be found a valuable medicine in the treatment of the latter affection. Commencing with a dose of two minims, we may gradually increase it to five; and it will be suitably prescribed diluted with an ounce and a half of water and a drachm of tincture of calomba every eight hours.

In conclusion, we refer the reader to the article Indigestion, in which the various disorders of the stomach commonly classed under the term dyspepsia have been fully discussed, and particularly to the third section of that article, which describes pyrosis in relation to them, under the head of *irritable gastric dyspepsia*.

William Kerr.

RAPE.—The high value set upon female purity, and the heavy penalty incurred by its loss, in the banishment of the delinquent from society, have led most civilized countries to inflict the severest punishments on the individual guilty of a forcible violation of the weaker sex. When we consider, on the one hand, the condition of a virtuous female thus plunged into an abyss of misery, a release from which by death has been voluntarily sought by many; and, on the other, contemplate the number of profligate persons who are found in all countries and societies, whose chief occupation seems to be the corruption and debasement of the female sex; we cannot fail to rejoice that the strong arm of the law should interpose its protecting shield, and visit with its severest judgments one of the grossest crimes that vice can perpetrate. By the law of England, rape is defined to be the carnal knowledge of a woman against her will, and death is its penalty. All classes of females are equally protected, the virgin, the married woman, and even the common prostitute is included, because she may at the very time have determined on a reformation of her former habits. In Scotland the ravisher is exempted from the pains of death, only in case of the woman's subsequent consent, or her declaration that she yielded of her own free will; and even then he is to suffer an arbitrary punishment either by imprisonment, confiscation of goods, or a pecuniary fine. (Edin. Encyclop. vol. xi. p. 823.) In the state of New York, death was formerly the punishment for committing a rape on a married woman or a maid; and it was also ordained at the same time, that if a woman had been ravished, and afterwards consented to her ravisher, her husband, father, or next of kin, might sue by appeal against such offender. These laws, however, have been repealed, the punishment altered, and appeals of felony abolished. The acts now in force prescribe the punishment of imprisonment for life in the State-prison, of the offender and his accomplices, if he have any, for ravishing by force any woman-child of the age of ten years and upwards, or any other woman. An assault, with an intent to commit a rape, may be punished by fine and imprisonment, or both.

[It has also been enacted that every person who shall have carnal knowledge of any woman above the age of ten years, without her consent, by administering to her any "substance or liquid," which shall produce such stupor or such imbecility of mind or weakness of body as to prevent effectual resistance, shall, upon conviction, be punished by imprisonment, in a State-prison, not exceeding five years.

In Massachusetts, Rhode Island, Delaware, and South Carolina, it is a capital offence. In Connecticut, Georgia, Illinois, Indiana, Ohio, Maine, New Hampshire, New Jersey, Vermont, Pennsylvania, Virginia, and Michigan, imprisonment for a term of years, or for life, is directed; in Louisiana, imprisonment and hard labour for life; and in the States of Missouri and Arkansas, the punishment is castration. (Beck's *Medical Jurisprudence*, 5th edit., i. 160, Philad. 1838.)]

In the case of adults, it is necessary, in order to constitute a rape, that the act shall have been committed against the will of the female; but in the case of children, in whom the power of judging between right and wrong is not supposed to exist, the matter of consent is of no moment, and the deed is equally criminal whether it be obtained or not. "A female infant under ten years of age is in law deemed incapable of consenting to any act, much less to her dishonour; the carnal knowledge of such infant, whether she yield or not, is therefore virtually a rape; but whether if the child be above ten years of age, it be also a felony, has been questioned. Sir Matthew Hale was of opinion that such profligate actions, either with or without consent, amount to rape and felony, as well since as before the statute of Queen Elizabeth; but in his Summary, the learned judge appears to have altered his opinion; and the present practice is, that if the child be under ten years of age then it is felony by the statute; but if she be above ten and under twelve, then it is no rape if she consented, but only a misdemeanour." (*Paris and Fonblanque*, Med. Jur. vol. i. p. 419.) The French code extends the period to fifteen years, and punishes the crime committed on a child of that age by hard labour for a limited time. (*Capuron*, p. 1.) "In New York the carnal knowledge of a woman-child under ten years of age is punished by imprisonment in the State-prison for life. In Massachusetts and Illinois, death is the punishment. In Virginia, New Hampshire, Connecticut, and New Jersey, impri

sonment either for life or a long term of years is directed. All these specify the period of ten years. The law in Vermont varies from this. It directs that whenever any individual over the age of fifteen shall abuse any female under eleven with or without her will, he will suffer fine and imprisonment." (*Beck*, p. 60.)

[It would appear that the punishment of death is awarded for this offence in only one State of the Union—Massachusetts. In Virginia, Connecticut, New Hampshire, Maine, New Jersey, Illinois, Ohio, Michigan, and Tennessee, the punishment is either imprisonment for life, or a term of years, or fine, or imprisonment, or both. All these specify the period of ten years. In Indiana, the age of the female is extended to twelve years, and the punishment is imprisonment for a term of years. In Missouri, a rape on a female under the age of ten years is punished by castration. In Delaware, the law directs a fine, standing in the pillory for one hour, sixty lashes on the back,—well laid on,—imprisonment for not more than two years, and afterwards to be sold as a servant for a term not exceeding fourteen years. (Beck, *op. cit.* i. 153.)]

By the ancient law of England, the woman was required to make her accusation immediately after the commission of the outrage. At a subsequent period she was allowed forty days as the utmost limit; but by the law as it at present stands, there is no time of limitation fixed. However, although there is no limit fixed by law, public opinion demands an early discovery; and an accuser who has postponed her complaint for any unreasonable length of time, is listened to with great caution by a jury. In fact, this is a crime so easily charged, so hard to be proved, and so much harder to be rebutted, that it is of the utmost importance that no time shall be allowed for concocting a malicious tale, particularly if medical testimony is to be adduced, as a few hours are often sufficient to efface appearances that might have been evident on an early examination. Indeed, in all cases, the greatest caution is necessary in judging of the guilt of an accused party. There is generally no witness to confirm the direct testimony of the accuser as to the fact; the whole case turns upon the woman's assertion, and unless there is strong collateral evidence, such as a speedy disclosure to her friends and the authorities, and an early medical examination, we are of opinion that it should require the clearest and most unshaken testimony on the cross-examination to gain credence with a jury. It is better that ten guilty should escape than that one innocent man should suffer: and however we abhor the crime, and would wish the heaviest punishment to overtake the guilty, we cannot help offering this caution to medical men and jurors, knowing as we do the depravity of the human heart, and the lengths to which it will sometimes go to accomplish the ends of malice or revenge. It is not impossible, nay, it has sometimes happened, that a woman who has freely consented to surrender her virtue will afterwards turn round on her paramour, and denounce him as her ravisher. This becomes a case of the greatest intricacy from the fact of the principal feature (that of the venereal congress having taken place) being true. It now passes out of the hands of the medical jurist, and becomes a question with the jury whether they believe the deposition of the woman as to consent or not. This, it must be confessed, is a most difficult question to solve, and it requires all the ingenuity of the bar to sift to the bottom all external circumstances which may contribute to prove the negative. Cases of a mixed kind are also sometimes met with; as when a woman will at first resist the advances of a suitor, and even continue her resistance for a time, but afterwards, from the excitement of passion or some other cause, yields to his desire. This is a case, if possible, more puzzling than the former, because marks of violence on the limbs of the female, from her previous struggling, may be evident, which would naturally lead to the supposition that the act had been accomplished by force. We confess that we should be inclined to deal hardly with a man under such circumstances, from the difficulty of understanding what constitutes consent. The act is committed in secret; there are no witnesses; the woman is bruised on the limbs and body; and her person is violated: it is not likely that a formal question of "Will you consent?" has been put, followed by an answer of yea or nay; and yet, after the employment of so much force, the man defends himself by saying the woman consented, which she denies. The jury alone can determine which is to be credited; but, as we already said, appearances are strongly in favour of the woman, and a struggle of such violence and duration, followed by coition, amounts, in our opinion, if not to a legal, at least to a moral rape. Having spoken thus generally of some of the difficulties attending the investigation of accusations of rape, we proceed to consider some of the points upon which medical testimony is more particularly required.

Of the physical Signs of Violation.—These are the absence of the signs of virginity, marks of violence, tumefaction, or laceration of the pudenda, with effusion of blood, and bruises on other parts of the body, particularly on the breasts, arms, and thighs. It must be evident that the most important of these, that is, the want of the attributes of the virgin state, together with the injuries inflicted on the genital organs, as evidenced by inflammation and tumefaction, cannot apply to all women, but only to virgins; for in married women, or those previously in the habit of sexual intercourse, the negative signs are of course of no value, and the positive are not likely to occur. And this narrows our present observations to the signs of rape committed on virgins.

The investigation of this subject must be preceded by an exposition of the signs of virginity. This is a question which has occupied the attention of anatomists and physiologists from an early period; but it does not appear that any very accurate conclusions have been agreed upon.

The existence of the hymen is the sign upon which the greatest stress has been laid by some authors, while, strange to say, its presence has been esteemed by others, among whom we find Ambrose Paré, Columbus, Dionis, and Buffon, as an unnatural formation. However, at the present day, it is generally considered as an attribute of the human virgin. The hymen is a membranous or membrano-carneous structure.

which is situated at the entrance of the vagina, and serves to form a boundary between that passage and the external genitals. It is formed by duplicatures of the lining membrane of the vagina, and is usually of a crescentic form, leaving an opening into the vagina at its upper part. This opening serves as an outlet for the menses, and in the average of adult subjects is large enough to admit the index finger sufficiently high up into the vagina, to effect an examination of the os uteri, without injury to the hymen. Dr. Davis states that in breech presentations he has sometimes introduced his finger into the vagina of the infant without injuring this membrane. The shape of this membrane, however, is various and uncertain. In some cases it is more or less circular, presenting through its centre a round aperture of three or four lines in diameter. At other times only a part or exclusive portion of the orificial extremity of the vagina, sometimes the superior, at other times the inferior portion of it, is seen to be veiled over with this structure. In some rare cases the hymen is an imperforate circular membrane attached to the edge of the orifice of the vagina in every part, so as to close the canal completely. We have already alluded to some of these cases in the article IMPOTENCE. Another form of the hymen is, when there are two crescental portions attached to the more carneous structure of the external orifice laterally. The structural tissue of the hymen seems in some measure to vary in different instances. "In most fœtal subjects it seems to be distinctly membranous, whilst in some others it partakes also of a carneous character. Hence, probably, the very different descriptions given of it by different authors. By Soranus it is accordingly described as being membranous; by Avicenna as veinous and ligamentous; by Riolanus as carneous; by Berengarius as retiform, consisting of vascular and delicate ligamentous tissue; by Columbus as a thick substance; and by Spigelius as partly carneous and partly nervous." (Princip. and Pract. of Obstet. Med. by Dr. Davis, p. 100.) In order to see this membrane in the living subject, it is necessary to separate the labia and even the thighs to a considerable distance from each other; for the opening into the vagina is quite closed up by the external parts in the ordinary positions of the body. The hymen is usually torn by sexual intercourse, and its rupture is attended by an effusion of blood; an appearance upon which so much reliance was placed by the Jews as a test of virginity, that the nuptial sheets were constantly exhibited to the relations on both sides, and preserved by the friends of the woman as evidences of her chastity. In case this token of virginity was not found on them, she was to be stoned to death at her father's door. After the rupture of the hymen, its remains shrivel towards their base into several small excrescences at the orifice of the vagina. These are thick, red, and obtuse at their extremities, and from their fancied resemblance to a myrtle-berry, have been called *carunculæ myrtiformes*. They generally disappear after frequent connections or deliveries. The carunculæ which are found at the opening of the vagina are not, however, always remains of the hymen. Dr. Conquest (Outlines of Midwifery, p. 17,) remarks that the carunculæ may be found when the hymen is entire. Dr. Davis (Loc. cit. p. 101,) observes that the greater part of the circle at the basis of the hymen when that structure remains, and at the same locality when it has suffered rupture, may occasionally be seen studded with caruncles of different origin; such extra caruncles in some cases being few and small, but in others large and numerous. He alludes to one case, which was that of a young lady of unquestionably good character, who, in consequence of some irregularities imputed to a gay husband, to whom she had been recently married, became the subject of a professional examination: there presented at the orifice of the vagina on either side, and in immediate contiguity to the caruncules remains of the hymen, two large multifoliated masses of structure, disposed in parallel layers in such a manner as scarcely to fail to suggest the idea of a pair of epaulettes. These are the forms under which the hymen is usually found; but it should be borne in mind by the medical jurist that it is liable to certain malformations, with which he should be acquainted. It is commonly a thin membrane, easily ruptured by any large body introduced into the vagina. But it sometimes occurs that it is possessed of so much firmness as to resist the intromission of the penis This unusual degree of thickness and strength may belong to a hymen composed of one uniform membrane; or to that conformation of it termed cribriform, from its being pierced by a number of holes. In this latter condition the membrane is commonly exceedingly strong, and capable of resisting the ordinary means of rupture. It is a state, however, that does not prevent impregnation, some cases of which are related by Dr. Davis; and as they relate to an important medico-legal point, we refer to them, in addition to those already mentioned in the article IMPOTENCE. One of these cases of cribriform hymen we transcribe in consequence of its great interest: "It was usually narrated in his peculiarly terse style by the late Dr. Haighton, in his lectures on midwifery in Guy's Hospital. The subject of it had been the lady of one of the physicians to that or to the neighbouring hospital of St. Thomas. It was become matter of post-mortem history even in the time of Dr. Haighton. The hymen was perforated by many small apertures; but it nevertheless was so strong that it had resisted all the efforts of the husband to effect its rupture. That gentleman, however, concealed his chagrin; nor did he take any means to accomplish artificially what he had failed to do by the ordinary means. Under these circumstances the lady drooped and became unhappy; but she also, at no distant period, became the subject of faintings and sickness, and eventually of great abdominal enlargement, and of anasarca of her lower extremities. During the urgency of those symptoms she was advised to go to Bath for the benefit of the waters and of the other good things to be obtained at that celebrated city. No remedy was found, however, even there for the lady's dropsy, and the symptoms became more and more urgent every day. Finding no relief at Bath, and giving up all hope of recovery any where, she determined, after a residence of some weeks at that place, to return

to London, in order that her remains might the more conveniently be deposited in the monumental vault of her family. Whilst on this journey, which she was performing in a post-chaise, she was seized with a severe abdominal pain, which she naturally enough ascribed to a spasm of the intestines. This colic, which was moderate and bearable at the commencement, became so extremely violent in its progress that she was obliged to stop suddenly at an inn on the road, where in less than an hour she was radically cured of her dropsy by becoming the mother of a well-grown living child. The hymen was then ruptured without the assistance of art." (Op. cit. p. 104.)

We have alluded to these cases to show that it is possible for all the moral guilt of a rape to be incurred without the conditions necessary to satisfy the law upon the point, namely, intromission of the penis, &c. Besides these sources of difficulty presented to the medical jurist in malformation of the hymen, there are some cases, and probably not a few, in which this membrane has never existed at all; or having been at first formed of great tenuity, has been ruptured and destroyed in early life. Accidental circumstances may also serve to obliterate it, such as disease, improper practices, or acrimonious discharges; and instances are not wanting where it has been destroyed by the pressure of the confined menstrual fluid. From the cases alluded to above, it appears that impregnation may take place without rupture of this membrane, but in these instances perforation is not supposed to have occurred. It is, however, stated by Zacchias that intromission may be effected when a disproportion exists between the organs, when the hymen does not exceed the ordinary size, but is thick and hard, and when connection has taken place during the presence of menstruation, or fluor albus, without damage to this membrane. Gavard (Foderé, Méd. Lég. t. iv. p. 340,) found it perfect in a female thirteen years of age, who was labouring under the venereal disease. Ruysch (Observ. Anat. Chirurg. xxii.) has said, that if coitus take place during or immediately after the menstrual excretion, this membrane is often not ruptured.

From these several circumstances of variety in the original formation and appearance of the hymen, its power of resisting the natural means of rupture in some cases, and its yielding in others to the slightest force, we are inclined to think that the accuracy necessary in forming a medico-legal opinion cannot be attained by looking to this sign alone. We must, however, agree with Dr. Beck (Elem. of Med. Jur. by Darwall, p. 52,) that it would be difficult to support an accusation of rape where the hymen is found entire, although its presence cannot be considered as an unequivocal proof of virginity; for, as we have stated, it has been asserted by good authority that it is not always ruptured in coitu. An instance is related by Dr. Smith (Prin. of For. Med. p. 410,) in which an accusation of rape fell to the ground in consequence of the presence of this membrane. This occurred in the case of a man named Stewart, who was tried at the Old Bailey in 1704 for ravishing two female children. The evidence being at variance as to the fact of penetration, the children were sent out of court to be examined, and the eldest was found to have the signs of virginity.

The state of the vagina is the next point worthy of consideration. In young subjects it is extremely small; but as the female advances towards puberty, it becomes increased in its dimensions. In a healthy adult virgin the parietes of the vagina are remarkably firm and substantial, and from the only function it has to perform, that of giving exit to the menstrual excretion, it is rigid and narrow. The internal surface is lined with a mucous membrane which is remarkable for the peculiarity of being much wrinkled or folded together into shallow irregularly transverse rugæ, the peculiar use of which is to qualify the passage for being indefinitely developed during parturition. These folds are removed by frequent sexual intercourse, and nearly obliterated in women who have borne one or two children. The dilatation of the vagina, and smoothness of its internal surface, are not, however, to be taken as unequivocal proofs of want of chastity, for these appearances may arise from other causes. There are disorders of which the tendency is to render it so, as fluor albus, chlorosis, or menorrhagia; and certain malpractices will also occasion the same dilatation as sexual intercourse; and, on the other hand, coitus may have taken place, and the vagina afterwards reassume its contracted condition.

Generally speaking, in virgins the external labia are thick, firm, elastic, and internally of a bright red colour, with their edges so opposed as to exclude the entrance into the vagina; while in married women, or those accustomed to coition, they are soft, pale, and have an interval of greater or less extent between them. But these signs will be found to vary according to the age, temperament, and state of health of the individual. Thus, in persons of a sanguine temperament, although in the habit of venereal enjoyment, the colour, firmness, and thickness of these parts will be preserved; and virgins of advanced age and weak leucophlegmatic habit of body, or those afflicted with leucorrhœa or menorrhagia, may present appearances which, if he above signs were supposed to be valid, would lead to a conclusion of an opposite character. The same observations will apply to the state of the frænum labiorum, or posterior commissure of the pudenda. Some authors have esteemed the integrity and rigidity of this part as a proof of virginity, but no positive conclusion can be drawn from it, for it frequently remains untouched even after parturition.

From the observations just made, we feel ourselves compelled to acknowledge that there are no anatomical signs by which we can attest the presence of virginity. Taken singly they are all fallacious, and even viewed in connection, they can only favour the conclusion as to the chastity of the female; but the converse is not established by the absence of these signs, as they may be all absent from causes already enumerated, although their absence may serve to corroborate the opposite opinion in suspected cases.

[M. Devergie (*Médecine Légale*, 2de édit. i. 345, Paris, 1840) has entered at length into an inquiry, founded on numerous examinations, as to the normal condition of the genital organs, in young children; in young girls near the period of puberty; in women who have had sexual intercourse; and in those who have had children;

and he lays great stress on the circumstance, that there is a considerable separation between the labia at their upper part in young children ;—the reverse occurring after puberty, and especially in those who have had sexual intercourse.]

Signs of Defloration.—In this inquiry it is necessary to take into account the age, strength, and state of mind of both persons concerned. The sexual organs of both should be examined, and this as speedily as possible after the alleged assault, for if the woman have reached the period of puberty, no satisfactory information can be obtained by a professional examination unless made immediately after the commission of the act. In children, from the great disproportion of the parts, the violence is greater, and the effects consequently remain for a longer time ; but in a subject of full organic development, the appearances consequent to connection are very fleeting. If the examination be made early, and particularly if the female have been a virgin, besides the state of mental excitement in which she may be found, there may be physical signs consisting in local marks of violence. The parts are found lacerated, tumefied, and bloody or inflamed, and painful to the touch; the hymen most commonly ruptured; and sometimes the presence of semen can be detected. Besides these marks upon the genitals, there are usually bruises or ecchymoses on other parts of the body, particularly on the arms, thighs, nates, and breast. In children the local appearances are more evident, from the greater injury the parts have received; and the inflammation is sometimes so great as to incapacitate them from walking. But in married women, even a very speedy examination will fail to afford much assistance, from the previously dilated condition of the parts. It should be borne in mind that the female genitals are liable to diseases which may imitate the appearances just pointed out. Of this fact, a case related by Dr. Percival (Medical Ethics, p. 103 and 231) is a striking example. A girl, four years of age, and in good health, was suddenly seized with inflammation of the pudenda, and symptoms of defloration, with pain in making water. She had slept two or three nights in the same bed with a boy fourteen years old, and had complained of being very much hurt by him during the night. The symptoms increased in violence, and the child died on the ninth day. An inquest was held on the body, and Mr. Ward, under whose care the patient had been in the Manchester Infirmary, deposed that death was caused by external injury. A verdict of murder was returned against the boy, and he was accordingly taken into custody. A very short time afterwards, however, several similar cases occurred in the same neighbourhood, in which there was no ground for supposing that violence had been offered. Fortunately for the boy, his trial had not come on, and Mr. Ward now informed the authorities of the mistake he had committed, and the prisoner was discharged. This kind of disease appears to be to a certain extent epidemic, and is very fatal. Thus, out of twelve cases mentioned by Mr. Kinder Wood, (Med. Chirur. Trans. v. vii. p. 84,) only two recovered. It is usually preceded by febrile symptoms for two or three days, and when the genitals are examined, they are found inflamed and swollen. The colour is dark, and ulceration with gangrene quickly follows The fever assumes a typhoid character, and death shortly takes place.

The presence of the venereal disease in the female, when its invasion corresponds with the period at which the outrage is stated to have occurred, that is, in from three to eight days afterwards, is a very strong corroborative proof of defloration, if the aggressor is found on examination to be afflicted with the same disease. This is not uncommonly the case in young children, in consequence of a very prevalent notion entertained by the lower orders, that connection with a virgin is a certain cure for the disorder. Appearances resembling gonorrhœa, however, should be looked at with a very scrupulous eye, as it is now perfectly well known that children, particularly those of strumous delicate constitutions, are liable to purulent discharges from the vagina, which very much resemble the consequences of impure connection. These discharges take place during dentition, or from the presence of worms in the intestinal canal, and are also sometimes observed in the male sex from the same causes. We are indebted to Sir Astley Cooper (Lectures on Surgery) for the following energetic observation on this peculiar affection. "There is a circumstance on which I am exceedingly anxious to dwell—I allude to a discharge from young females, and I hope that there is not one here this evening but will be strongly impressed with the importance of the subject. Children from one year old, and even under, up to puberty, are frequently the subjects of a purulent discharge from the pudendum, chiefly originating beneath the preputium clitoridis; the nymphæ, orifice of the vagina, and the meatus urinarius, are in an inflamed state, and pour out a discharge. The bed-linen and rest of the clothes are marked by it. It now and then happens to a nervous woman to be alarmed at such an appearance, and she suspects her child of having acted in an improper manner; and perhaps not quite clear herself, she is more ready to suspect others, and says, dear me, (if she confesses,) it is something like what I have had myself. She goes to a medical man, who may unfortunately not be aware of the complaint I am speaking of, and he says, 'your child has got a clap.' I can assure you a multitude of persons have been hanged for such a mistake. I will tell you exactly what takes place in such cases; the mother goes home and says to the child, 'who is it that has been playing with you? who has taken you on his knee lately?' The child innocently replies, 'no one, mother, nobody has, I declare to you.' The mother then says, 'Oh, don't tell me such stories; I will flog you if you do.' And thus the child is driven to confess what never happened, in order to save herself from being chastised ; at last she says, 'Such a one has taken me on his lap.' The person is questioned, and firmly denies it; but the child, owing to the mother's threats, persists in what she has said. The man is brought into a court of justice; a surgeon who is ignorant of the nature of the discharge I am now speaking about, gives his evidence; and the man suffers for that which

he never committed. The mother is persuaded, if there be a slight ulceration on the parts, that violence has been used, and a rape committed.

"If I were to tell you how often I have met with such cases, I should say that I have met with thirty in the course of my life. The last case I saw was in the city; a gentleman came to me, and asked me to see a child with him who had a gonorrhœa on her. I went, and found that she had a free discharge from the preputium clitoridis. I said that there was nothing so common as this. There was considerable inflammation, and it had even proceeded to ulceration, which I told him would soon give way to the use of the liquor calcis with calomel. 'Do you tell me so?' he replied; 'why, suspicion has fallen on one of the servants; but he will not confess. If he had appeared at the Old Bailey, I should have given my evidence against him; for I was not aware of what you have just told me.' I told him that if the man had been hanged by his evidence, he would have deserved to be hanged too. I am anxious that this complaint should be known by every one present, and that the remarks which I have made should be circulated throughout the kingdom. When a child has this discharge, there is a heat of the parts, slight inflammation; and this sometimes increases, and goes on to ulceration. This disease sometimes occurs in children at the time of cutting their teeth."

In the year 1831 a man was arrested in the city of Dublin on a charge of a rape committed on a child; the only evidence of which was the presence of a purulent discharge from the pudendum. Popular opinion, as is usual in such cases, ran high against him; and it was only through the positive opinion of an intelligent surgeon that the case was explained, and the man liberated. A case of a somewhat similar nature lately came under the observation of the writer. A lady and gentleman came to his house one evening in a state of great alarm and excitement, accompanied by their child, a girl of four years old, whom they stated to be afflicted with a terrible disorder, communicated to her by some person in their employment. They had previously shown the child to an apothecary, who confirmed their worst apprehensions, and at once declared that the girl had got a clap. On examination, the parts were found in a state resembling that just described, with a free purulent discharge; and it was with no small degree of pleasure the writer was able to console the parents by assuring them that their child was labouring under no uncommon affection, and that a few days would set all to rights. It has rarely fallen to his lot to witness a more sudden transition from grief to joy than this announcement effected.

Dr. Ryan (Med. Jur. p. 185,) mentions the case of a delicate girl, aged 11 years, who had a purulent discharge from the external genitals, and accused a young man of eighteen, whose genitals were developed in an extraordinary degree, of having violated her person. Two apothecaries swore the girl had been violated, a rape committed, and gonorrhœa communicated. Dr. Gordon Smith, Mr. Whitmore, and Dr. Ryan were of a different opinion. The case was grievously mismanaged for the prisoner; the only evidence produced in his favour was Dr. Smith's, which was contrasted with that of the two medical witnesses for the prosecution, who had refused to examine the person of the prisoner, although assured that he had no discharge from the urethra, and had not had any for six months previously. The man was found guilty at the Middlesex sessions, and sentenced to six months' imprisonment, and lectured by the chairman on his good fortune that he was not hanged. The mother of the child confessed to Dr. Smith that she had had the discharge since she was five years old.

[In a recent article (*Lond. and Edinb. Monthly Journal of Med. Science*, Sept. 1844, p. 760,) Dr. J. R. Cormack has described similar cases which lead him to the practical conclusion, "that a variety of causes, constitutional and local, may (either singly or in conjunction with one another) give rise to discharges, which cannot be distinguished from those occasioned by impure coitus, to which the name of gonorrhœa is commonly applied."]

From these and other similar instances, we cannot too strongly urge the necessity of an early examination of both parties. By following this course, it has happened that the man has been acquitted where marks of disease were discovered in the female, because no signs of gonorrhœa have been detected about himself. A case related by Sir Matthew Hale (*Paris and Fonblanque*, Med. Jur. vol. i. p. 418,) furnishes an instance where an innocent man might have been saved from a malicious prosecution, to the hazard of his life, by this precaution. Foderé (Méd. Lég. vol. iv. p. 363,) mentions two cases from Zacchias, where the falsehood of an accusation was determined by a comparative inspection of both parties. Besides the presence or not of disease, there are other points to be determined by examination. Thus it may happen that the man is impotent; the penis may have been lost by sloughing, accident, design, or cancer; the female organs may be so constructed as to prevent the possibility of penetration; in all of which cases an inspection of both parties can alone give grounds for conclusive opinions. It has been remarked by a writer in a celebrated periodical work, with reference to the purulent discharge of what we have just spoken, that "we must take care not to run into the opposite error of ascribing inflammation, ulceration, and discharge in cases where violence has been alleged, to this disease without sufficient grounds; for it is extremely improbable that diseases which occur so rarely should happen to appear in a child to whom violence was offered, unless that violence had some effect in producing it." (Edin. Med. Surg. Journ. vol. xiii. p. 491.) On this point we think it right to observe that the laceration, tumefaction, and inflammation consequent to the violation of a child are very different from the disease under consideration, and could scarcely be confounded with it. Its great resemblance is to true gonorrhœa; and that point can be settled by a personal examination of the man accused. Dr. Dewees (Treat. of Children, pp. 236, 435,) states that when this disease arises in very young subjects, it almost always proceeds from a neglect of cleanly attention to these parts, either by withholding a frequent use of lukewarm water, or permitting the child to remain too long wet. Children, however, of a more advanced age

have also discharges of a purulent character, that seem to arise from a morbid action of the mucous membrane of the vagina. This frequently shows itself about the fifth year, and may continue, if neglected, to almost any period. It should be recollected that violence has been sometimes inflicted on the external genitals for the purpose of sustaining an accusation against an innocent person. A remarkable case of this sort is related by Foderé. A female at Martigues, in 1808, accused eight or ten of the principal persons of the place of having violated her grand-daughter, aged about nine years and a half, at an inn. She laid her complaint before the judge de paix, and stated that she would withdraw it provided the accused would accommodate the matter with her. She had procured a daughter of the inn-keeper, aged sixteen and an idiot, as a witness. As the charge was obstinately persisted in, Foderé, with two officers of health, was ordered to examine the child in presence of the judge; and suspicion was immediately excited from the delay used in admitting the visitors. On examining the parts, he found the hymen untouched, and the vagina extremely narrow. Around the pudenda, however, a red circle about the size of a crown was observed, which appeared to have been induced recently; and this was indeed the fact; for at the end of half an hour the circle had decreased in size, and the redness disappeared. Had this been the effect of great violence, it is natural to suppose that it would have increased in intensity of colour. A report was prepared, stating the above facts; and the consequence was, that the accuser was put in prison, and finally ordered out of the city.

The chief point in an accusation of rape, necessary to be proved, is the act of coition; but as considerable difference of opinion has existed as to what legally constitutes this act, it is necessary to make some observations upon it. Some authorities have maintained that simple penetration was sufficient, while others have judged that without emission the crime is not complete. In the case of Russen, the schoolmaster, who was tried for a rape committed on a girl under ten years of age, it was proved by two surgeons on behalf of the prisoner, and corroborated by four others who had examined the girl, that the hymen (which they considered an indubitable mark of virginity) was whole and unbroken, and that the passage was so narrow that a finger could not be introduced. But Mr. Justice Ashurst, who tried the case, left it to the jury whether any penetration were proved; for if there were any, however small, the rape was complete in law. The jury found him guilty, and he received judgment of death. But before the time of execution, the matter being much discussed, the learned judge reported the case to the other judges for their opinion, whether his directions were proper; and upon a conference it was unanimously decreed that the directions of the judge were perfectly right. They held that, in such cases, the least degree of penetration was sufficient, though it may not be attended with the deprivation of the signs of virginity. It was, therefore, properly left to the jury by the judge; and accordingly, the prisoner was executed. This occurred in the year 1777. On the other hand, Lord Coke, Sir Matthew Hale, and Hawkins held that there must be both penetratio and emissio seminis, and this appears to have been the decision of Skynner, C. B. Gould, Willis, Ashhurst, Nares, Eyre, and Hotham, against Lord Loughborough, Buller, and Heath; Lord Mansfield, though present, having given no opinion of his own. The argument is stated to have turned on the words carnal knowledge, to which the majority contended that emissio seminis was absolutely necessary. (*Paris and Fonblanque*, Med. Jur. vol. i. p. 433.) This state of the law rendered cases of rape extremely difficult to prove; for in virgins it is not at all likely they would be conscious of any such circumstance having taken place, particularly when we consider the state of fright, pain, and weakness into which they are necessarily thrown; and even in married women it does not appear that they are always conscious of emission—indeed, we should be inclined to suppose the reverse. Judge Buller stated, in giving judgment on a case in 1787, that he recollected a case where a man had been indicted for a rape, and the woman had sworn that she did not perceive anything come from him; but she had had many children, and was never in her life sensible of emission from a man. Again, in the case of children, it is manifestly impossible that evidence of emission can be obtained; and, as has been well remarked by Dr. Paris, if it be true that certain eunuchs have the power of erection, and consequently of penetration, they may morally ravish without incurring the punishment of rape; for it is certain that they can have no emissio seminis; or a man may have perpetrated all the more atrocious parts of his crime, and yet being interrupted in the least voluntary constituent of it, escape the well-merited vengeance of the law; while it is evident, on the other hand, that the innocent victim has suffered in body, mind, and reputation, as much as if the crime had been legally completed. (Loc. cit.) It has been stated in defence of this practice of requiring proof of emission, that it is quite necessary to make the proof of the crime difficult in order to avoid false accusations, for it often happens that the only chance an innocent man has is the cross-examination of the prosecutrix; if, therefore, it be necessary to prove all the circumstances, including emission, it follows that there is a greater likelihood of the witness tripping in her evidence.

The question with respect to requiring proof of seminal emission in cases of rape has been recently settled by an act (9 Geo. IV. c. 31, passed June, 1828,) which cites "that upon trials for the crimes of buggery and of rape, and of carnally abusing girls under the respective ages hereinbefore mentioned, offenders frequently escape by reason of the difficulty of the proof which has been required of the completion of these different crimes; for remedy thereof be it enacted, that it shall not be necessary in any of these cases to prove the actual emission of seed in order to constitute a carnal knowledge, but that the carnal knowledge shall be deemed complete upon proof of penetration only." By the same act the crime of rape, or of the abuse and carnal knowledge of a girl under ten years of age, is punishable by death. Abuse and carnal knowledge of a girl

between ten and twelve years of age is considered a misdemeanour only, punishable by imprisonment, with or without hard labour.

In Philadelphia, where the law is the same as with us, it has become common of late years to indict for an attempt to commit a rape, rather than for the crime itself, and chiefly from the difficulty of proof. Emission, however, is not considered essential in Pennsylvania (according to Judge Cooper); and properly, he adds, for it is not the essence of the crime, and it may happen without being perceived in cases of violence. In Illinois it is expressly enacted that so much of the law regulating the evidence in case of rape as makes emission necessary, is hereby repealed. (*Beck*, p. 67.)

[In the United States, the disposition, almost universally, is, to consider penetration alone to be sufficient evidence as to the *carnaliter cognovit;* and recent English decisions are to the effect, that the least possible introduction of the male organ within the orifice of the vagina,—even short of the rupture of the hymen, and without the emission of sperm,—constitutes a rape, provided it be done forcibly, and against the will of the female. (See 5 *Carrington & Payne's Reports*, 321; and *Ibid.* August 27, 1838; Regina *v.* Hughes, 1841, in *Ibid.* 9: cited in Guy's *Principles of Forensic Medicine*, p. 52, Lond. 1843.)

Of late years, great stress has been laid upon spots or stains on the linen of the accused, or of the woman; which, according to M. Devergie, (*op. cit.* i. 358,) afford, at times, the strongest proofs of violation. These spots are of two kinds, and occupy two different positions—the one on the anterior part of the chemise, and the other on the posterior. This, at least, is their most common situation. The spots on the front of the chemise present all the characters of sperm. They are of a greyish-white colour; circumscribed, roundish, and terminated at their circumference by a greyish line of a deeper colour. The linen is stiffened; and, if the effort to violate has been recent, the spots, even when dry, may exhale a spermatic odour; and, when subjected to analysis and microscopic examination, may furnish all the characters of sperm. The spots on the hind part of the chemise are most commonly formed of blood; but they usually occur under two different forms: the one, of a deep red, smaller, rich in colouring matter, and of an equal degree of colour over their whole surface; the other, of a much brighter red, or rather of a reddish yellow: larger than the first; paler at the centre, and bounded at the circumference by a circle of red colouring matter, deeper than the rest of the spot. The former are produced by pure blood extravasated at the time of the sexual union; the latter by a bloody serum, a sero-sanguineous oozing, less and less coloured, and altogether like that which flows from wounds made by a cutting instrument, when they cease to discharge blood. This respective position of the spots, M. Devergie adds, is not so constant but that spots of blood, or of sanguineous serum, may exist on the front of the chemise, and some drops of sperm on the back: but still they are more frequently seen under the circumstances described above.

Mr. Taylor (*Manual of Medical Jurisprudence*, p. 579, London, 1844) affirms, that cases of rape have hitherto been tried without reference to this species of evidence; and that it is not easy to perceive how this can be necessary to the proof of the crime, when the present law of England demands only proof of penetration, and not of emission. "Thus"—he says—"a rape may be legally completed without reference to emission; and, medically speaking, it appears quite possible that there might be emission without any penetration. Admitting that certain stains of this description are found on the clothes of an accused party, is this to be taken as an undeniable proof of the legal completion of rape? It appears to me that it cannot be so taken, and, therefore, that the affirmative evidence from the miscroscope is as liable to lead to error as that which is purely negative. Besides, if such evidence were either required or received, it is impossible to set a limit to the mistakes and fallacies into which a court of law might be led. It could only escape from these by receiving evidence from a practised microscopical observer. Among the reports of numerous trials for rape, in our courts, I have never yet met with a single instance in which such evidence was required, or would have been of the least utility." (P. 580.)

Great caution would, doubtless, have to be used in admitting such testimony: yet it is easy to see, that the fact of blood upon the clothes might be *primâ facie* evidence of violence, and the presence of sperm strongly indicate the object of such violence.

It need scarcely be said, that care must be had not to confound spots of blood with the stains produced by the menstrual discharge. Menstrual blood contains but little fibrin, and does not coagulate. It is probably, also, darker than that which would flow as the result of violence. By introducing a plug into the vagina, it could be discovered that the blood proceeds from high up that canal; which would at once show that it was not the result of violence, if any doubt previously existed. In case of suspected spots of sperm, by infusing the linen in water, and placing the fluid in the field of a microscope, if spermatozoa be perceptible, there will be no difficulty in arriving at a decision. Dr. Dewy (*Edin. Med. and Surg. Journ.* iv. 15) affirms that he observed them in a seminal stain which had been kept eighteen days; and still more extraordinary cases are on record. (Devergie, *op. cit.* iii. 347, and Guy, *op. cit.* p. 61.)]

This crime may be committed on a female at any period of life after she has passed mere infancy. We have already mentioned the law as applied to children. In this case the charge of violation requires the most accurate inquiry, because the material evidence in other cases, that of the sufferer herself, is wanting, from her being incapable as a witness in consequence of her youth. "If the rape be charged to have been committed on an infant under twelve years of age, she may still be a competent witness, if she hath sense and understanding to know the nature and obligation of an oath, or even to be sensible of the wickedness of telling a deliberate lie; nay, though she hath not, it is thought by Sir M. Hale, that she ought to be heard without oath, to give the court information; and others have held that what the child

told her mother or other relations may be given in evidence, since the nature of the case admits frequently of no other proof. But it is now settled by a solemn determination of the twelve judges, that no hearsay evidence can be given of the declarations of a child who hath not capacity to be sworn; nor can such child be examined in court without oath; and there can be no determinate age at which the oath of a child ought either to be admitted or rejected; but their admissibility depends upon the sense and reason they entertain of the danger and impiety of falsehood, which is to be collected from their answers to questions propounded to them by the court." (*Paris and Fonblanque*, vol. i. p. 421.) Females, before they reach the time of life at which menstruation commences, are generally ignorant of the consequences likely to result; and this, coupled with want of physical power, may often tend to facilitate the commission of rape. But at the age of puberty it has been doubted whether a woman of ordinary strength may not successfully resist the attempts of a single man.

Farr, in speaking of this subject, expresses himself in the following terms:—"But the consummation of a rape, by which is meant a complete, full, and entire coition, which is made without any consent or permission of the woman, seems to be impossible, unless some very extraordinary circumstances occur. For a woman always possesses sufficient power by drawing back her limbs, and by the force of her hands to prevent the insertion of the penis, whilst she can keep her resolution entire." (P. 41.) Dr. Beck quotes the following answer given by the medical faculty of Leipsic to the question whether a single man could ravish a woman: "Si circumstantias quæ in actu coëundi concurrunt consideramus, non credibile, nec possibile, videtur, quod unus masculus nubilem virginem (excipe impubem, teneram, delicatam, aut simul ebriam puellam) absque ipsius consensu, permissione atque voluntate vitiare, aut violento modo stuprare possit; dum feminæ cuilibet facilius est si velit, penis immissionem recusare, vel multis aliis modis impedire, quàm viro eidem invitæ planè intrudere." (Valentini Pandectæ, vol. i. p. 61.) It is necessary, therefore, to be extremely cautious in admitting the truth of accusations, unless the bodily power of the man far exceeds that of the complainant. At the same time, however, we should not entirely agree with the positive opinions just quoted, for we think it possible that by long-continued violence, intimidation, or other circumstances, the man may ultimately prevail.

The question naturally arises here, *can a female be violated without her knowledge?* in which case the crime would be equally great, for it would be still without her consent. There are different ways in which we may suppose this to be effected, as during natural sleep, or stupefaction caused by inebriation or narcotics, or during a fit. As to the possibility of rape being committed on a virgin during natural sleep, we are very much inclined to doubt it, notwithstanding the decision of the faculty of Leipsic, "Dormientem in sella virginem insciam defiorari posse." (Valentius, Novellæ Med. Leg. cas. 1.) When we consider the violence inflicted, and the pain that attends a first intercourse, we think it scarcely possible that any natural sleep could be so sound as to preserve the woman unconscious of what was going forward. The case is not exactly the same with married women, in whom from previous sexual intercourse the parts are more dilated. In such case we must admit the possibility, but not at all the probability, for even in them natural sleep, however heavy, would be most likely broken by the attempt at violation. That a female, whether virgin or not, may be ravished during the insensibility attending intoxication, the administration of narcotics, or disease, will be readily granted. As the sufferer can give no direct testimony as to the fact, the only corroboration to be obtained is from a personal examination; but as we have already mentioned, this can be of no use alone in the case of her being a virgin. There is reason to think that narcotics have not been unfrequently administered for the purpose of facilitating the commission of rape, which circumstance is justly considered a great aggravation of the offence, and, when proved, is sure to draw down the heaviest punishment on the perpetrator. A case occurred in Dublin, in April 1831, in which a gentleman was tried for a rape, and convicted, chiefly in consequence of an impression made on the minds of the jury, that some soporific had been administered by him to the young lady, by means of which he was enabled to effect his purpose. (Dublin Morning Post, April 20, 1831.) There is another mode in which this crime may be committed, wherein, although the woman is not unconscious, she makes no resistance, neither does she consent: that is, when a man obtains admission to the bedroom of a married woman, and imposes himself on her as her husband. This constitutes a case of rape, and subjects the offender to the usual penalty. The same holds good in the case of forcible abduction, where a woman is compelled to marry and is afterwards violated by force.

[Dr. Guy (*op. cit.* p. 64,) states, that in the year 1840, he was consulted by a poor woman, who, after mentioning other complaints of little importance, stated, that she was somewhat alarmed by the fact of her sleep being so heavy, that she was with difficulty aroused. She added, by way of illustration, that her husband had assured her that he had frequently had connection with her during sleep.]

The fact of sexual intercourse being proved or admitted, it now remains to be ascertained whether the woman consented or not. If she be dead, which sometimes happens from the violence employed, the most material part of the evidence, her own testimony, is of course wanting, unless she have lived long enough to give information before her death. In the well-known case of Abraham Thornton, who was tried some years ago, in England, for the murder of Mary Ashford, (a case remarkable for being the last in which a wager of battle was offered, such right having been immediately afterwards abolished by the statute 59 Geo. III. c. 46;) the prisoner admitted having had carnal knowledge of her, but stated that it was with her own consent; and although the general tenor of the evidence was in opposition to this assertion, the death of the unfortunate woman rendered it impossible to ascertain the truth. It was formerly

imagined that the occurrence of pregnancy after violation was evidence of the consent of the woman. This opinion was maintained by Dr. Bartley (P. 43,) and Dr. Farr (P. 43,) on the supposition that women under the influence of the depressing passions, such as fear, terror, &c. could not conceive. It is said by Mr. Dalton, that if a woman at the time of the supposed rape do conceive with child by the ravisher, this is no rape, for (he says) a woman cannot conceive unless she doth consent. Such an opinion was founded on the idea that a certain amount of enjoyment on the part of the female is necessary towards conception. But it has been clearly ascertained that this is not the case, and the process of impregnation may go forward, totally without the will, consent, or enjoyment of the female. "That so absurd a notion as that conception evidenced consent, should in modern times have obtained amongst any whose education and intellect were superior to those of an old nurse, is indeed surprising: at this day, however, facts and theory concur to prove that the assentation of nature in this respect is no ways connected with violation of mind." (Burn's Just. tit. Rape.) Such is the opinion of all medical jurists; and it is supported by the many facts on record, of impregnation having taken place in consequence of connection had with females during insensibility from disease or the influence of narcotics.

It was ruled, in the case of the king against Fleming and Windham (Leach's C. L. p. 996, and Paris and Fonblanque, vol. i. p. 439), A. D. 1779, that if the party be dead, the deposition of the girl, taken before the committing magistrate and signed by him, may after her death be read in evidence at the trial of the prisoner, although it was not signed by her, and she was under twelve years of age; provided she was sworn and appeared competent to take an oath; and all the facts necessary to complete the crime may be collected from the testimony so given in evidence. But, as is the practice in other criminal cases, it is not necessary that the female should be sworn, if her testimony is given while she is dying, she being conscious of her state at the time; for it is considered that the awful situation in which she is placed is as sure a guarantee of the truth as any form of oath could be. At the same time it is quite necessary to have proof of the soundness of her understanding at the time, for without this the solemnity of the occasion, and the anticipation of death, may not have a sufficient impression on her mind.
